ABSTRACT

Background

It is estimated that by 2020, road traffic crashes will have moved from ninth to third in the world ranking of burden of disease, as measured in disability adjusted life years. The prevention of road traffic injuries is of global public health importance. Measures aimed at reducing traffic speed are considered essential to preventing road injuries; the use of speed cameras is one such measure.

Objectives

To assess whether the use of speed cameras reduces the incidence of speeding, road traffic crashes, injuries and deaths.

Search strategy

We searched the following electronic databases covering all available years up to March 2010; the Cochrane Library, MEDLINE (WebSPIRS), EMBASE (WebSPIRS), TRANSPORT, IRRD (International Road Research Documentation), TRANSDOC (European Conference of Ministers of Transport databases), Web of Science (Science and Social Science Citation Index), PsycINFO, CINAHL, EconLit, WHO database, Sociological Abstracts, Dissertation Abstracts, Index to Theses.

Selection criteria

Randomised controlled trials, interrupted time series and controlled before-after studies that assessed the impact of speed cameras on speeding, road crashes, crashes causing injury and fatalities were eligible for inclusion.

Data collection and analysis

We independently screened studies for inclusion, extracted data, assessed methodological quality, reported study authors’ outcomes and where possible, calculated standardised results based on the information available in each study. Due to considerable heterogeneity between and within included studies, a meta-analysis was not appropriate.

Main results

Thirty five studies met the inclusion criteria. Compared with controls, the relative reduction in average speed ranged from 1% to 15% and the reduction in proportion of vehicles speeding ranged from 14% to 65%. In the vicinity of camera sites, the pre/post reductions ranged from 8% to 49% for all crashes and 11% to 44% for fatal and serious injury crashes. Compared with controls, the relative improvement in pre/post injury crash proportions ranged from 8% to 50%.
Authors’ conclusions

Despite the methodological limitations and the variability in degree of signal to noise effect, the consistency of reported reductions in speed and crash outcomes across all studies show that speed cameras are a worthwhile intervention for reducing the number of road traffic injuries and deaths. However, whilst the evidence base clearly demonstrates a positive direction in the effect, an overall magnitude of this effect is currently not deducible due to heterogeneity and lack of methodological rigour. More studies of a scientifically rigorous and homogenous nature are necessary, to provide the answer to the magnitude of effect.

PLAIN LANGUAGE SUMMARY

Do speed cameras reduce road traffic crashes, injuries and deaths?

Road traffic crashes are a major cause of death and disability. The speed at which a vehicle travels is an important determinant of injury; the faster the vehicle is travelling, the greater the energy inflicted on the occupants during a crash, and the greater the injury.

Excessive speed (driving faster than the posted limit or too fast for the prevailing conditions) has been found to contribute to a substantial number of crashes. It is predicted that, if the number of speeding drivers is reduced, both the likelihood and severity of a crash will be lowered. Therefore, interventions aimed at reducing traffic speed are considered essential to preventing road injuries and deaths. The enforcement of safe speeds with speed cameras and associated automated devices is one such measure.

To evaluate the effectiveness of speed cameras, the authors examined all eligible studies, that is, studies that met pre-set standard criteria. We analysed the effect of speed cameras on speeding, road traffic crashes, injuries and deaths by comparing what was happening in road areas before the introduction of speed cameras and after their introduction, and also by analysing what was happening in comparable road areas where no speed cameras were introduced during the study period.

The authors accepted a total of 35 studies for review which met the pre-set criteria. All studies reporting speed outcomes reported a reduction in average speeds post intervention with speed cameras. Speed was also reported as either reductions in the percentage of speeding vehicles (drivers), as percentage speeding reductions over various speed limits, or as reductions in percentages of top end speeders. A reduction in the proportion of speeding vehicles (drivers) over the accepted posted speed limit, ranged from 8% to 70% with most countries reporting reductions in the 10 to 35% range.

Twenty eight studies measured the effect on crashes. All 28 studies found a lower number of crashes in the speed camera areas after implementation of the program. In the vicinity of camera sites, the reductions ranged from 8% to 49% for all crashes, with reductions for most studies in the 14% to 25% range. For injury crashes the decrease ranged between 8% to 50% and for crashes resulting in fatalities or serious injuries the reductions were in the range of 11% to 44%. Effects over wider areas showed reductions for all crashes ranging from 9% to 35%, with most studies reporting reductions in the 11% to to 27% range. For crashes resulting in death or serious injury reductions ranged from 17% to 58%, with most studies reporting this result in the 30% to 40% reduction range. The studies of longer duration showed that these positive trends were either maintained or improved with time.

The quality of the included studies in this review was judged as being of overall moderate quality at best, however, the consistency of reported positive reductions in speed and crash results across all studies show that speed cameras are a worthwhile intervention for reducing the number of road traffic injuries and deaths. To affirm this finding, higher quality studies, using well designed controlled trials where possible, and studies conducted over adequate length of time (including lengthy follow-up periods) with sufficient data collection points, both before and after the implementation of speed cameras, are needed. As none of the studies were conducted in low-income countries, research in such settings is also required. There is a greater need for consistency in methods, such as international standards for the collection and reporting of speed and crash data and agreed methods for controlling bias in studies. This would allow more reliable study comparisons across countries, and therefore greater ability to provide stronger scientific evidence for the beneficial effects of speed cameras.

The pandemic of road traffic deaths and injuries continues unabated. Each year almost 1.2 million people die and between 20 and 50 million people are injured or disabled worldwide as a result of road traffic crashes (Peden 2004). For people under 44 years, road traffic crashes are a leading cause of death and disablment second only to HIV and AIDS (Krug 2002). The continuing advance of motorisation in many developing countries is likely to further exacerbate the problem. It is estimated that by 2020 road traffic crashes will have moved from ninth to third in the world ranking of burden of disease, as measured in disability adjusted life years (Murray 1997). In 2003, the annual cost of road traffic crashes to Australia for example, was more than $17 billion per annum, or approximately 2.3% of Gross Domestic Product (GDP) (Connelly 2006). This finding is consistent with other recent reviews of the costs of road traffic crashes in developed countries (Elvik 2000; Jacobs G 2000) in which the mean costs have commonly been found to be in the order of 2-3% of GDP. Thus, the identification of effective strategies for the prevention of road traffic injuries is of public health and public finance importance globally.

The relationship between speeding and crash rate, and speeding and injury rate has been examined in many studies and reviewed by the US Transportation Research Board (US TRB 1998). The relationship between speeding and the likelihood of crashing should be logical; increasing speed increases the reaction distance (the distance travelled while the driver is reacting to a situation) and the braking distance. In reality, the relationship between speeding and crash rate is not simple, but it is consistent across studies. In two-car crashes, the greater the deviation in speed from the average, the higher the rate of crashes. This relationship is thought to be due to increased interactions between vehicles when travelling at different speeds. In single-vehicle accidents, the higher the speed, the greater the risk of crashing. Whilst studies demonstrate that motorists travelling at both significantly higher and significantly lower than average speeds have a greater crash risk, it has also been highlighted that the relationship with lower speeds was due mainly to crashes involving turning and slowing vehicles (US TRB 1998; Aarts 2006). The relationship between speeding and injury rate is straightforward; the faster the vehicle is travelling, the greater the energy absorbed by the occupants during the rapid change in velocity that occurs during a crash.

Speed limits on roads are used to regulate traffic speed and thus promote road safety by establishing an upper limit on speed, and by reducing the variance (dispersion) of the speed of vehicles. As injury severity increases non-linearly in relationship to speed, curbing ‘top-end’ speeders should also reduce the number of deaths and severe injuries in those crashes that do occur. Speed limits are usually assigned by category, type, and design of the road (Chin 1999). The main purpose of speed limits is to regulate driving speeds to achieve an appropriate balance between travel time and risk (US TRB 1998). Many countries provide some type of enforcement to ensure that drivers obey the posted speed limits.

In Australia, during 2002, there were 1715 fatal crashes, of which 562 were identified as involving excessive speed (defined as driving faster than the posted limit or too fast for the prevailing conditions), using data obtained from the Australian Transport Safety Bureau (ATSB 2003). This finding is consistent with a 2004 report on fatality data from the United States which suggests that excessive speed likewise defined, is implicated in about 30% of all fatal crashes there (U.S. Department of Transportation 2004). It is predicted that, if the number of drivers who are speeding is reduced, both the likelihood and severity of a crash will be lowered (Pilkington 2002). The enforcement of speed limits must be sufficient to ensure that drivers believe that if they speed, they will be caught. Police cannot be present on all roads at all times and therefore, in many countries, there is increasing use of automatic speed enforcement, using detection devices (speed cameras) that may be manned or unmanned, mobile or fixed, as well as overt or covert. Most of the older speed camera systems rely upon 35 mm wet film, which necessitates regular extraction from the units, while the newer systems employ digital and video cameras and transmit the information over data networks. Most speed cameras use a low-powered doppler radar speed sensor that triggers the camera to photograph vehicles and capture the licence plate number of vehicles travelling above a preset speed. Automated speed enforcement cameras take single spot or average vehicle speeds over several measurements (Decina 2007).

Automatic speed enforcement has the capability of being a substantial net revenue-raising activity. This blurs the line for the public as to whether governments use the device for safety or for fiscal reasons, and may harden attitudes towards their use. Some people view the introduction of speed cameras as a violation of their civil liberties. Legal issues, such as whether the owner or the driver of a vehicle is responsible for the speeding violation, also arise. The arguments for and against speed cameras have been highlighted in British Columbia, Canada. The trial by (Chen 2000) concluded that the introduction of cameras had reduced speeding, with a corresponding decrease in crashes, injuries and fatalities. Nevertheless, in June 2001, the speed camera program was discarded by the incoming government. However, most countries that have introduced speed cameras have tended to expand their use over time. This is particularly noticeable within the United Kingdom and Australia.

The aim of this systematic review was to determine whether the use of speed detection devices reduces the incidence of speeding, crashes, injuries and deaths. A secondary consideration was to examine the relative effectiveness of covert versus overt cameras, halo effects, and mean and actual speeds. Little empirical evidence currently exists for the relative effectiveness of covert detection devices versus devices that can be seen. It is thought that while overt cameras should reduce speeds at road crash ‘black spots’ (also called

**BACKGROUND**

The relationship between speeding and crash rate, and speeding and injury rate has been examined in many studies and reviewed by the US Transportation Research Board (US TRB 1998). The relationship between speeding and the likelihood of crashing should be logical; increasing speed increases the reaction distance (the distance travelled while the driver is reacting to a situation) and the braking distance. In reality, the relationship between speeding and crash rate is not simple, but it is consistent across studies. In two-car crashes, the greater the deviation in speed from the average, the higher the rate of crashes. This relationship is thought to be due to increased interactions between vehicles when travelling at different speeds. In single-vehicle accidents, the higher the speed, the greater the risk of crashing. Whilst studies demonstrate that motorists travelling at both significantly higher and significantly lower than average speeds have a greater crash risk, it has also been highlighted that the relationship with lower speeds was due mainly to crashes involving turning and slowing vehicles (US TRB 1998; Aarts 2006). The relationship between speeding and injury rate is straightforward; the faster the vehicle is travelling, the greater the energy absorbed by the occupants during the rapid change in velocity that occurs during a crash.

Speed limits on roads are used to regulate traffic speed and thus promote road safety by establishing an upper limit on speed, and by reducing the variance (dispersion) of the speed of vehicles. As injury severity increases non-linearly in relationship to speed, curbing ‘top-end’ speeders should also reduce the number of deaths and severe injuries in those crashes that do occur. Speed limits are usually assigned by category, type, and design of the road (Chin 1999). The main purpose of speed limits is to regulate driving speeds to achieve an appropriate balance between travel time and risk (US TRB 1998). Many countries provide some type of enforcement to ensure that drivers obey the posted speed limits.

In Australia, during 2002, there were 1715 fatal crashes, of which 562 were identified as involving excessive speed (defined as driving faster than the posted limit or too fast for the prevailing conditions), using data obtained from the Australian Transport Safety Bureau (ATSB 2003). This finding is consistent with a 2004 report on fatality data from the United States which suggests that excessive speed likewise defined, is implicated in about 30% of all fatal crashes there (U.S. Department of Transportation 2004). It is predicted that, if the number of drivers who are speeding is reduced, both the likelihood and severity of a crash will be lowered (Pilkington 2002). The enforcement of speed limits must be sufficient to ensure that drivers believe that if they speed, they will be caught. Police cannot be present on all roads at all times and therefore, in many countries, there is increasing use of automatic speed enforcement, using detection devices (speed cameras) that may be manned or unmanned, mobile or fixed, as well as overt or covert. Most of the older speed camera systems rely upon 35 mm wet film, which necessitates regular extraction from the units, while the newer systems employ digital and video cameras and transmit the information over data networks. Most speed cameras use a low-powered doppler radar speed sensor that triggers the camera to photograph vehicles and capture the licence plate number of vehicles travelling above a preset speed. Automated speed enforcement cameras take single spot or average vehicle speeds over several measurements (Decina 2007).

Automatic speed enforcement has the capability of being a substantial net revenue-raising activity. This blurs the line for the public as to whether governments use the device for safety or for fiscal reasons, and may harden attitudes towards their use. Some people view the introduction of speed cameras as a violation of their civil liberties. Legal issues, such as whether the owner or the driver of a vehicle is responsible for the speeding violation, also arise. The arguments for and against speed cameras have been highlighted in British Columbia, Canada. The trial by (Chen 2000) concluded that the introduction of cameras had reduced speeding, with a corresponding decrease in crashes, injuries and fatalities. Nevertheless, in June 2001, the speed camera program was discarded by the incoming government. However, most countries that have introduced speed cameras have tended to expand their use over time. This is particularly noticeable within the United Kingdom and Australia.

The aim of this systematic review was to determine whether the use of speed detection devices reduces the incidence of speeding, crashes, injuries and deaths. A secondary consideration was to examine the relative effectiveness of covert versus overt cameras, halo effects, and mean and actual speeds. Little empirical evidence currently exists for the relative effectiveness of covert detection devices versus devices that can be seen. It is thought that while overt cameras should reduce speeds at road crash ‘black spots’ (also called
covert cameras should reduce speeds over a wider area (Keall 2001). Likewise, other questions that need to be answered centre upon the so-called ‘halo’ effects. For example, the length of time an effect of enforcement is present after detection devices have been removed is known as the time-halo. The distance-halo is the distance from the point of speed enforcement that the decrease in speed continues. Regarding speed, speed cameras may lower the mean (relative) speed on the road (for example, the mean speed could fall from 110 km/h to 107 km/h in a 100 km/h zone), or they may lower the top speeds (absolute) on the road (for example, the top speed may be 150 km/h pre camera and 130 km/h post camera in a 100 km/h zone). This review considered both types of speed reduction.

To ensure the highest possible level of evidence available, in the absence of randomised controlled trials, studies selected for this review included only before-after trials with control or comparison areas and interrupted time series studies. This is in contrast to the only other systematic review of speed cameras (where standardised calculated results were reported) which included both controlled and uncontrolled before-after studies (Pilkington 2005).

**OBJECTIVES**

The objective of this systematic review was to investigate whether speed enforcement detection devices lower:

- the percentage of speeding drivers on the road;
- the absolute speeds above the speed limit;
- the rate and severity of injurious crashes on the road.

**METHODS**

**Criteria for considering studies for this review**

**Types of studies**

Studies were included if they involved any of the following research designs:

- randomised controlled trials (RCTs) (including clustered RCTs and quasi-RCTs);
- controlled before-after studies (CBAs);
- interrupted time series studies (ITSs).

The definition of CBA and ITS designs are based on that used by the Cochrane Effective Practice and Organisation of Care group (EPOC) as follows:

- CBA: A design where there is contemporaneous data collection before and after the intervention and an appropriate control site or activity;
- ITS: A design where there is a clearly defined point in time when the intervention occurred and at least three data points before and three after the intervention.

All reasonable efforts were made so that the inclusion of trials was not restricted by language or publication status.

**Types of participants**

Drivers of all motorised vehicles.

**Types of interventions**

All automated and semi-automated methods and systems available for speed enforcement were considered. This included speed cameras (photo radar) laser and other radar devices as well as ancillary equipment such as road embedded electromagnetic loops. These types of interventions can be further categorised into either manned or unmanned; mobile or fixed, overt or covert cameras or a combination of these.

As the effect of co-intervention is difficult to exclude in studies such as these, studies that did not have the aforementioned speed enforcement devices as the major intervention focus were not eligible for inclusion.

This systematic review does not cover interventions by red light cameras at signalised junctions, as this topic has been addressed by another Cochrane systematic review, available from the Cochrane library (Aeron-Thomas 2005).

**Types of outcome measures**

- Percentage of speeding drivers above the speed limit or designated speed threshold, and their average speeds in areas with and without cameras: to investigate the overall effect of the enforcement.
- The absolute pre/post change in speed or the percentage pre/post change in speed in areas with and without cameras.
- Duration of speed reduction (i.e. time and distance halos): to investigate the local and widespread effects of the enforcement.
- Crash and injury outcomes: All road user deaths and injuries and all road traffic crashes. Our definition of ‘road users’ included drivers and their passengers, cyclists and pedestrians.

**Search methods for identification of studies**

The searches were not restricted by date, language or publication status.
Electronic searches

We used the following methods for identification of studies, searching mainly transportation, educational and medical electronic databases:

- Cochrane Injuries Group Specialised Register (April 2004 and June 2009)
- Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews (the Cochrane Library)
- MEDLINE (via WebSPIRS 1962 to May 2010)
- EMBASE (via WebSPIRS 1995 to May 2010)
- TRANSPORT (includes the Transport Research Information Services (TRIS), The International Road Research Documentation (IRRD) and The European Conference of Ministers of Transport (TRANSDOC) databases) (1968 to September 2009);
- Web of Science (Science (and Social Science) Citation Index 1981 to September 2009);
- PsycINFO (1980 to September 2009)
- CINAHL (1982 to September 2009)
- EconLit (1990 to November 2004)
- Dissertation Abstracts (1990 to October 2004)
- Index to Theses (1985 to August 2009)

Search strategies are further reported in Appendix 1.

Searching other resources

Handsearches

We handsearched the journals Accident Analysis and Prevention (1974 to April 2010) and Injury Prevention (1995 to April 2010).

Internet searches

We searched the web sites of a number of road safety organisations, a full list is presented in Appendix 2.

We set up a daily Google Alert, now Giga Alert (April 2004 to June 2010). The following search words were found to be the most effective combinations, accounting for the greatest number of relevant hits:

- speed camera study
- automatic enforcement speed* study
- speed camera before after study
- speed camera before after control*
- safety speed camera trial study
- speed roads control* before and after study
- speed* camera* injury accident crash* speed camera road study
- speed camera halo effect, safety speed camera enforce*
- speed* camera* collision* crash* trial* speed* camera* injury*
- before after, study* speed* camera* police, safety camera enforce* control

The settings for Google Alert allowed these search words to be further utilised by restricting the search to different time frames and/or countries. Certain search words used for other databases such as photo radar and laser were quickly abandoned in Google due to the large amount of irrelevant and advertising materials they generated.

British Medical Journal (BMJ) customised alerts (weekly) was also set up using the search terms randomised controlled trials, controlled trial, before and after studies, speed or safety camera, road crashes, road injury and their related thesaurus terms.

Unpublished studies

In an effort to identify unpublished studies we contacted experts in the field and searched national registers for ongoing trials. We attempted to identify further potential published or unpublished studies by checking references of relevant articles, reviews and books and by contacting authors of relevant papers where possible.

We contacted international and national road safety organisations as well as voluntary agencies with an interest in road safety. We also scanned daily newspaper and online news reports (for example, BBC news online (daily)) for references to relevant articles.

Conference proceedings

We searched the following conference proceedings:

- Road Safety Research, Policing and Education Conference - www.rsconference.com:2004
- Road Traffic Injuries and Health Equity Conference 2002 Massachusetts www.hsph.harvard.edu/traffic/papers.html;
- Road Safety on Three Continents Conference South Africa 2000 www.vti.se/pdf/reports/K15A.pdf;
- 7th World Conference on Injury Prevention and Safety Promotion Vienna 2004
- 9th World Conference on Injury Prevention and Safety Promotion Mexico 2008

Data collection and analysis
There were five stages of the review process.

**Stage 1: Identification of studies for inclusion**

One author (CW) initiated the original search for trials. A second author (CMW) continued the search, finding titles, abstracts and landmark reports in the road safety research literature. Based on potential relevance deduced from reading abstracts, full studies were obtained and short-listed if appropriate for assessment.

**Stage 2: Selection of studies for inclusion**

Relevant studies selected from the process in stage one were independently assessed against the inclusion criteria by three authors (CMW, CW, RLB). Investigators were contacted where possible for any additional information regarding trials that potentially fulfilled the inclusion criteria.

**Stage 3: Data Extraction**

Data were independently extracted from the included studies by four of the authors (CMW, CW, JH, RLB) using a standardised form, which was piloted before use. Data were extracted on the following key elements:

- study design;
- study length and data collection details;
- setting of the study and nature of the roads;
- types of interventions used;
- characteristics of intervention and control sites;
- measures of exposure and outcomes;
- description and treatment of bias and confounding;
- analyses and results.

Following data extraction, any differences or disagreements between reviewers were resolved by detailed discussion leading to consensus (CMW, CW, JH, RLB, NB). Where necessary and possible, additional information was sought from study authors.

**Stage 4: Quality Assessment**

The assessment of the quality of non-randomised trials is problematic. Controlled before-after studies (CBAs) and interrupted time series studies (ITSs) are acknowledged as methodologically weaker than randomised controlled trials, and few if any validated quality assessment instruments exist for non-randomised studies. Having perused the literature for validated tools, and discussed the issue at length with experts in the field, we decided to use a quality assessment process based on the Data Collection Checklist described by the Cochrane Effective Practice and Organisation of Care Review Group (EPOC).

Quality assessment and scoring was performed independently by three authors (CMW, CW, RLB). The process was based on four of the seven criteria used for the quality assessment for CBA designs, and the two additional criteria for ITS designs, used by EPOC. The criteria chosen were those that are relevant to community trial designs and specifically determine the appropriateness of baseline measurements, characteristics of the control site, protection against contamination between sites, and reliability of the outcome measures, including: objectivity of measurement, results being reported with random variability and p-values, important potential confounders and risk of bias described and controlled for, and discussion of study generalisability. ITS studies were also scrutinised against the EPOC quality criteria of a clearly defined point in time when the intervention occurred, and at least three data collection points before and after the intervention. All disagreements were resolved by consensus. Table 1 in the ‘Additional Tables’ section provides a list of the included studies with their individual quality grade.

### Stage 5: Syntheses of results

In order to facilitate the comparison of studies as well as to capture the effect of intervention(s) and relate them to control (non-intervention) data, a standardised and well-defined summary measure was devised. These summary measures were calculated where possible i.e. if required information was reported or adequate data was available for calculation. The tool selected was based on relative effects, rather than difference in effect, where the outcome after intervention is divided by that before intervention as an expression of the proportional change in the outcome.

Unadjusted data provided by study authors in their tables, text or on graphs was used to present results in relation to speed, numbers speeding, crashes, injuries and fatalities. In addition to study traits and outcome data in the ‘characteristics of included studies’ table, the results and further information were also presented in the Summary of findings for the main comparison and Summary of findings 2, which show speed and crash outcomes from CBA studies. These tables show the outcomes reported by the study authors’ and also those calculated by our review author JH which consisted of standardised calculated results where possible and the study information that the latter were based on. Studies that reported both speed and crash results were highlighted with an asterisk in the tables. Summary of findings 3 show outcomes from the ITS studies consisting of the study authors’ results, the outcome(s) analysed, statistical method, standardised calculated results where necessary (calculated by review author JH) and information that the latter were based on as well as quality grade.

### CBA studies

The following descriptive summary statistics were used as the outcomes (speed and crash outcomes) for CBAs.

#### Speed

**Relative speed ratio (RSR)**

$$\text{RSR} = \frac{\text{average speed post intervention}}{\text{average speed pre intervention}} \times \frac{\text{average speed pre control}}{\text{average speed post control}}$$

When expressed as a percentage, RSR measures the relative percentage change in speed after intervention i.e. relative to control.

**Percentage Speeding Relative Rates Ratio (PSRRR)**

$$\text{PSRRR} = \frac{\text{speeding rate post intervention}}{\text{speeding rate pre intervention}} \times \frac{\text{speeding rate pre control}}{\text{speeding rate post control}}$$

When expressed as a percentage, PSRRR measures the relative percentage change in speeding rates after intervention i.e. relative to control.

This applied to the percentage of vehicles speeding or percentage of speeders who were speeding in excess of a speed threshold.

#### Crashes (all crashes, injurious crashes and fatal crashes)

**Relative Crashes Ratio (RCR)**

$$\text{RCR} = \frac{\text{crashes post intervention}}{\text{crashes pre intervention}} \times \frac{\text{crashes pre control}}{\text{crashes post control}}$$

When expressed as a percentage, RCR measures the relative percentage change in crash numbers after intervention i.e. relative to control.
that for control. It is the same as the odds of crashing after intervention relative to the same odds if there were no intervention i.e. an odds ratio.

**Percentage Crashes Relative Risks Ratio (PCRRR)**

\[
\text{PCRRR} = \frac{\text{crash risk post intervention}}{\text{crash risk pre intervention}} \times \frac{\text{crash risk pre control}}{\text{crash risk post control}}
\]

When expressed as a percentage, PCRRR measures the relative risk of crashing post intervention, compared with pre-intervention, relative to that for control. This applies to the percentage of vehicles crashing.

95% confidence intervals (CI) were included in parentheses. For all descriptive summary statistics, values less than 1 indicate a relative reduction, i.e. relative to control result. This reduction can be expressed as a percentage improvement using \((1 - \text{summary statistic}) \times 100\%\).

In the case where the above descriptive statistics or CI were not supplied by the studies, but where there was sufficient other information, these were calculated. Statxact was used if data required exact methodology.

Weighted averages across strata were calculated unless weights were not supplied, in which case crude averages are used. Mean ratios were calculated using geometric means.

**ITS studies**

Interrupted time series analyses were conducted in six studies (AU VIC 1; CA British Columbia; ES Barcelona; GB Cambridge; GB Nationwide; NZ Nationwide). The statistical analytical method used for ITS studies ranged from simple monthly averages pre and post intervention to more advanced methods such as ARIMA or multivariate regression using generalised linear models. Within a study, these analyses were performed for different outcomes and for different constructs or strata. For both speed and crashes, most ITS studies reported a calculated or estimated percentage change in the outcome after intervention, which they commonly defined as,

\[(\text{Post intervention estimate} - \text{Pre intervention estimate}) \times 100 \% \]

Meta-analysis was not appropriate for this review due to pronounced heterogeneity and consequently we could not test for publication bias. For the same reason, we were unable to perform any reasonable subgroup analyses on the various types of SEDs e.g. overt versus covert camera issues.

**RESULTS**

**Description of studies**

See: Characteristics of included studies; Characteristics of excluded studies.

After full text review of all potentially relevant studies, 35 studies met the inclusion criteria. All studies were observational in nature of which, 29 were controlled before-after trials (CBAs) incorporating a distinct control or comparison group(s) and six were interrupted time series studies (ITSs) with a comparison group(s). Seven studies had associated studies, which were subsumed in each of the seven primary studies. No randomised controlled trials were found.

As heterogeneity was widespread across studies we have included examples of variations in Table 2 in the 'Additional Tables' section of this review, to make it easier for the reader to note differences between studies.

</table>
Two studies reported halo effects, with three studies describing time halo effects (AU NSW 1; CA Toronto; NO Oslo) two studies reported distance halo effects (AU Tasmania; FI Finland) and one study (AU NSW 2) reported both time and distance halo effects.

Outcome measures in the studies differed considerably and included various definitions and measures of speed, crashes, injuries and deaths. For some studies, results for ‘all crashes’ may be inclusive of property damage crashes, and it should be borne in mind that injury crashes are not always necessarily a subset of those that are speed related (assuming such crashes can actually be defined).

Most studies analysed crash numbers rather than rates and only a few studies provided data on the aggregate (over crashes) of the number of fatalities and number of people, who sustained at least one injury.

Types of interventions varied between studies. Speed enforcement detection devices (SEDs) were described according to whether they were overt or covert, whether they were operated from a fixed or mobile position on the road, or any combination of these four elements. For the purposes of this review, fixed SEDs were defined as speed cameras operating from a fixed mounted position on permanent poles and did not include speed cameras operating from patrol cars or working on temporarily installed poles. The latter, although stationary for a period were often moved from place to place. Seventeen studies assessed the effect of fixed cameras, of which, 16 studies had overt SEDs and one study had both overt and covert SEDs. Fifteen studies assessed the effect of mobile camera interventions. Of these, eight studies had overt and three had covert SEDs. Four studies had both a mixture of overt and covert SEDs. Two studies reported the effects from a combination of both fixed and mobile overt SEDs, and one study reported the effects of a combination of fixed, mobile, overt and covert SEDs.

Studies also varied considerably in both the number and duration of intervention events. Interventions were continuous in only two of the studies. Continuous operation was defined as SEDs operating continuously at all experimental sites and did not include SEDs operating continuously at some sites on a random alternating basis.

All included studies took place in high income countries, with one study each from Denmark, Finland, Germany, Hong Kong and Spain, two each from the Netherlands, New Zealand and Norway, three from Canada, five from the United States of America, six from the United Kingdom and 10 from Australia. Thirteen studies were conducted within an urban setting, six in a rural setting, seven occurred in a rural and/or a semi-rural location and nine studies were conducted within a mixed urban/rural/semi-rural environment. This diversity of study locations corresponded with a range of urban, semi-rural and rural speed limits within studies, that varied from 40 kilometres per hour (km/h) through 60 km/h, 80 km/h, 100 km/h and 110 km/h to corresponding speed limits in miles per hour (mph) in the UK and USA. Only eight studies described their criteria for speed limit compliance, above which traffic infringement notices were issued.

All included studies were published between 1984 and 2009, with study periods ranging from nine weeks to thirteen years; twelve trials had study periods of less or equal to 24 months, seven had study periods of 25 to 48 months (2+ to 4 years), nine had study periods of 49 to 72 months (4+ to 6 years), one of 73 to 96 months (6+ to 8 years), three of 97 to 120 months (8+ to 10 years) and three of equal or greater than 120 months (10 years plus). The major focus for studies of the shortest duration was the measurement of halo effects.

More detail about individual studies can be found in the table ‘Characteristics of included studies’.

Risk of bias in included studies

Four of the seven criteria outlined in the data collection checklist described by the Cochrane EPOC Review Group were used to establish the methodological quality of the included controlled before-after studies:

1. availability of baseline measurements;
2. appropriate choice of control;
3. protection against contamination between intervention and control site;
4. reliability of outcome measures.

Table 2. List of variations between studies (some examples) (Continued)

<table>
<thead>
<tr>
<th>9+ years (1)</th>
</tr>
</thead>
</table>

Because several studies emanated from the same country and some studies had one or more main authors in common, it was decided that naming studies according to the official country codes of the International Organisation for Standardisation (ISO-3166) was the clearest naming option.

Nineteen studies reported both speed and crash outcomes (AU NSW 2; AU NSW 3; AU Tasmania; AU VIC 1; AU VIC 2; CA British Columbia; CA Vancouver B.C.; DE Germany; DK Denmark; FL Finland; GB 30mph Roads Nationwide; GB Nationwide; HK Hong Kong; NL Friesland; NL Netherlands; NZ Christchurch; NZ Nationwide; US Arizona 1; US North Carolina). Nine studies reported only crash outcomes (AU QLD 1; AU QLD 2; AU VIC 3; ES Barcelona; GB Cambridge; GB Norfolk; GB South Wales; GB West London; NO Nationwide) and seven studies reported only speed outcomes (AU NSW 1; AU Queensland; CA Toronto; NO Oslo; US Arizona 2; US Maryland; US Washington DC). Of the included studies, six studies reported halo effects, with three studies describing time halo effects (AU NSW 1; CA Toronto; NO Oslo) two studies reported distance halo effects (AU Tasmania; FI Finland) and one study (AU NSW 2) reported both time and distance halo effects.
In addition to criteria 1) and 4) above, two other criteria as described by EPOC were used to assess the methodological quality of ITS studies, which were, a clearly defined point in time when the intervention occurred, and at least three data collection points before and after the intervention. The criteria for CBA provided twelve key indicators in total, and the criteria for ITS studies provided a total of nine key indicators. The outcomes for the scoring method used to assess the methodological quality of the included studies can be viewed in Table 1. CBA studies were marked as either done, not clear, not done (as described by EPOC) for each of the twelve indicators, and again ITS studies were marked as either done, not clear, or not done for each of the nine indicators.

For studies to be then classified as high quality, moderate or low quality, the scoring was as follows:

CBA studies: High = (Done = 10, Not clear = 2, Not done = 0), Moderate = (Done = 8, Not clear = 2, Not done = 2), Low = (< 8 Done).

ITS studies: High = (Done = 7, Not clear = 2, Not done = 0), Moderate = (Done = 6, Not clear = 2, Not done = 1), Low = (< 6 Done).

The overall quality of the studies was assessed as low to moderate. Of the 35 included studies, only 12 studies were scored as being of high quality. Of the remaining 23 studies, 12 were scored as moderate and 11 were scored as low.

See the notes section in the 'Characteristics of included studies' table for concerns with specific studies. Additional information can also be found in the 'Summary of findings tables'.

Effects of interventions

See: Summary of findings for the main comparison Summary of findings - Speed Outcomes (CBA); Summary of findings 2 Summary of Findings - Crash Outcomes (CBA); Summary of findings 3 Summary of Findings - ITS studies

Calculated summary statistics and brief descriptions of speed and crash outcomes were presented for individual trials where appropriate.

Speed

All studies reporting speed outcomes reported an absolute reduction in average speeds post intervention. Reductions were reported either as mean speeds, ‘average speeds’ or as median speeds. Most studies, thirteen in total, reported mean speeds (AU NSW 2; AU NSW 3; AU Tasmania; CA Vancouver B.C.; DK Denmark; GB 30mph Roads Nationwide; GB Nationwide; NL Friesland; NZ Nationwide; US Arizona 2; US Maryland; US North Carolina; US Washington DC). The reduction in mean speeds ranged from 1.3km/h in New Zealand to 5.8 km/h in New South Wales, with most countries showing reductions in the 2 to 4 km/h range. For countries expressing speed in miles per hour, the mean speed reduction ranged from 6% in the United Kingdom nationwide to 14% in Washington D.C. Average speeds were reported by three studies (AU VIC 2; NL Netherlands; NO Oslo) and showed speed reductions ranging from 0.9km/h to 5 km/h. Median speeds were reported by two studies (AU South Australia; DE Germany) with the former reporting a speed reduction of 5km/h and the latter recording reductions in median speeds of 40km/h and 28 km/h in car lanes, and a 23km/h reduction in the truck lane on the motorway after 10 years of continuous automated enforcement. The standardised summary statistic relative speed ratio (RSR) that is, the relative percentage change in average speed after intervention i.e. relative to control could be calculated for nine of the studies (AU NSW 2; AU Tasmania; NL Friesland; NL Netherlands; NZ Nationwide; US Maryland; US Arizona 2; US North Carolina; US Washington DC). From these studies, fourteen RSR results could be calculated which ranged from 0.85 to 0.99, indicating that relative post-pre reductions were an improvement on ‘control’ i.e. control arm(s) by between 1% to 15%. For eight of the RSRs, there was insufficient information to calculate confidence limits (CL). Of the remaining six RSRs, using CL as an indication of statistical significance, two RSRs were significant and four non-significant (Summary of findings for the main comparison).

Percentage speeding

Speed was also reported as either absolute reductions in the percentage of speeding vehicles, as percentage speeding reductions over various speed limits, or as reductions in percentages of top end speeders. Eight standardised summary statistic percentage speeding relative rates ratio (PSRRR) could be calculated for eight studies (AU NSW 1; CA British Columbia; FI Finland; NL Friesland; NL Netherlands; NZ Nationwide; US Maryland; US Washington DC) and ranged from 0.35 to 0.86, indicating reductions of 14% to 65% relative to controls. For five of the PSRRRs there was insufficient information to calculate confidence limits (CL). Of the remaining three PSRRRs, using CL as an indication of statistical significance, two RSRs were significant and one non-significant (Summary of findings for the main comparison).

An absolute reduction in the proportion of speeding vehicles (drivers) over the accepted posted speed limit, ranged from 8% in Finland to 70% in New South Wales, with most of the twelve countries reporting this outcome, in the 10 to 35% range. For the proportion of vehicles exceeding the speed limit by more than 10 mph, an 82% absolute reduction was reported in the (US Washington DC) study. The calculated PSRRR was 0.35 (95% CI 0.30 to 0.40) indicating that the reduction was a significant improvement over that for controls. The Maryland study (US Maryland) reported a 70% reduction; PSRRR 0.52 (CI incalculable) and the North Carolina study (US North Carolina) saw a 55% reduction (PSRRR incalculable) (GB Nationwide) reported a 43% reduction for vehicles exceeding the speed limit by more
than 15 mph. For countries reporting in kilometres per hour the reduction for vehicles exceeding the speed limit by more than 10 km/h ranged from 4.5% in Denmark to an 88% reduction in New South Wales. Hong Kong reported a reduction of 65% for those exceeding the speed limit by more than 15 km/h and Victoria (AU VIC 2) saw a 76% reduction in vehicles exceeding the speed limit by more than 30 km/h post implementation of the speed camera program. Further details of speed outcomes can be seen in the ‘Characteristics of included studies’ section and in Summary of findings for the main comparison and Summary of findings 3.

**Halo effects**

Two important measures of the local effect of automated enforcement on the speed distribution are the time halo and distance halo. The effect of the distribution of speeds at and around the site of enforcement whilst the enforcement takes place is known as the distance halo. The time halo is the effect on the distribution of speeds after the enforcement activity has been terminated. As the characteristics of studies, where a primary focus was the reporting of halo effects varied in terms of location, duration of intervention, data collection and measurement, a brief overview of each of the six studies that reported these halo effects is as follows:

- **New South Wales (AU NSW 1)** - Outcome = Time halo of at least two days.
  - Study period from February 1982 for a period of nine weeks. Two experimental sites with police car stationed at both sites. The primary survey point was 300 metres downstream at site two where the experiment was covert. The secondary point was 200 metres upstream at site one, where the experiment was overt. The sites were in two lane sub-arterial urban roads with a 60km/h speed limit. Enforcement symbol in place and enforcement period was for one hour in the morning 8.00am to 9.00am and one hour in the afternoon 2.00pm to 3.00pm in February and March 1982.
  - Oslo (NO Oslo) - Outcome = Time halo up to eight weeks during daylight hours, in 80 km/h zones three out of five measured time intervals showed a time halo effect of six weeks.
  - Five patrols each consisting of one marked vehicle and two police officers, average nine hours of enforcement per day (388 hours of enforcement in six weeks). Continuous speed measurement for 24 hours every day during the sixteen week study period. Experimental road was a 35 km stretch of undivided two lane road in a semi-rural area divided into six sections for the experiment (control similar).
  - **Toronto (CA Toronto)** - Outcome = Three day time halo for one dose of enforcement.
  - At least six days time halo for five consecutive doses of enforcement.
  - Study period October 1979 to December 1979; five week study. Data collection by 2.5 hours per day on weekdays of five consecutive weeks for each location. Automatic speed traffic data recorders were used. Four experiments are described. The four experiments differed in the number of days of enforcement. Each experiment consisted of measuring speed of vehicles before, during and after enforcement took place. Each of the four experimental sites had an ‘upstream’ enforcement and a ‘downstream’ measurement site (latter was 1km to 2.5 km from the site of enforcement). In experiment 1 the police van was visible in advance. In experiment 2 to 4 the police vehicle was visible to the driver only 200 to 300m before passing the speed sensors.
  - **New South Wales (AU NSW 2)** - Outcome = Time halo at least one day after enforcement, distance halo up to 14 km downstream.
  - Study period December 1986 to March 1987 for speed.
  - Thirty-two sites of enforcement, aerial speed surveillance. From the 32 rural sites in place by December 1986, 10 experimental sites were chosen. Five matched control sites were selected.
  - **Tasmania (AU Tasmania)** - Outcome = Distance halo up to 22 km.
  - Total study length was two years between December 1984 to December 1986.
  - Single overt police car, random scheduling low intensity enforcement for two hours per day, seven days per week at sites. Location was three rural or main roads with a 110 km/h speed limit divided into one km sections.
  - **Finland (FI Finland)** - Outcome = Distance halo 3 km upstream to two km downstream. Study period April 1990 to December 1993.
  - Cameras rotated randomly between 12 camera poles at a distance of 1.5 km to 7 km from each other in one direction of enforcement.
  - Duration of surveillance from 8 to 36 hours (operation time 8065 hours from April 1992 to December 1993).

**Crashes**

All studies reported a reduction in road traffic crashes and crashes resulting in injury post speed camera intervention. The magnitude of this effect in crash outcomes varied considerably across studies. Crash outcomes were reported by twenty eight studies in total, of which, localised effects (that is, at or in the vicinity of camera sites) were reported by eleven studies. Twenty studies reported on generalised effects and three of the twenty eight studies reported both localised and generalised effects.

**Localised crash effects**

The result for ‘all crashes’ showed pre/post percent reductions ranging from 8% in Victoria (AU VIC 1) to about 49% in Arizona (US Arizona 1) with all other studies reporting this outcome showing reductions in the 14% to 25% range. For crashes resulting in deaths or serious injuries pre/post percent average reductions of 11% at or less than 500m distance and 13% at or less than 1km distance were reported by (GB 30mph Roads Nationwide), reductions of 11.5% were seen in Victoria (AU VIC 2) and reductions of 38%, 42% and 44% were reported by (AU QLD 2;
GB Nationwide and GB Norfolk) respectively. Whilst a pre/post reduction of 22% in personal injury crashes at camera sites was found in one large study in (GB Nationwide) no significant reduction in injury crash frequency or severity was found within one km of camera sites, either in urban or rural areas, in another sizeable study in Victoria (AU VIC 1) as a result of camera site operations. However in this latter study a localised effect of 8.4% in pre/post injury crash reduction was found for all urban roads as a result of the influence of receipt of traffic infringement notices (TINs). A reduction of about 50% in injury crashes was reported by South Wales (GB South Wales) and the Cambridge study (GB Cambridge) reported a pre/post 45.74% reduction in injury crashes within 250m from camera sites and a lesser but significant 20.86% reduction inside a 2 km radius from the camera.

Generalised crash effects

Outcomes reported were pre/post reductions in ‘all crashes’ ranging from 9% in Christchurch (NZ Christchurch) to 35% in the Netherlands (NL Netherlands), with all other studies reporting reductions in the 11% to 27% range. For crashes resulting in death or serious injury pre/post percent reductions ranged from 17% in British Columbia (CA British Columbia) to 58% in Tasmania (AU Tasmania) with all other studies reporting this outcome in the 30% to 40% reduction range. For injury crashes pre/post percent reductions ranged from 17% in British Columbia (CA British Columbia) and New Zealand (NZ Nationwide) to 23% reductions for Denmark (DK Denmark) and Hong Kong (HK Hong Kong).

For the outcome ‘all crashes’ 14 relative crash ratio (RCR) could be calculated for 12 studies and ranged in value from 0.53 (95% CI = 0.39-0.73) in Arizona (US Arizona 1) to 0.95 (95% CI = 0.73-1.22) in Vancouver (CA Vancouver B.C.) denoting reductions of 5% to 47% for ‘all crashes’ relative to controls. Using CI as an indication of statistical significance, eight RCRs were significant and six were non-significant. The RCR could be calculated for 11 studies reporting ‘injury crash’ results and ranged from 0.57 (95% CI = 0.32-1.03) in Arizona to 0.86 (95% CI =0.42-1.02) in Hong Kong (HK Hong Kong), of which two were significant and nine non-significant. For the few studies (4) where the RCR could be calculated for ‘fatalities’, the result ranged from 0.00 (95% CI =0.00-0.35) in New South Wales (AU NSW 2) to 0.72 (95% CI = 0.36 -1.08) in Tasmania (AU Tasmania). In the GB 30mph Roads Nationwide) study both fatal and serious injury crashes were reported together. The RCR in this latter study, for at or less than the 500km distance was 0.69 (95% CI = 0.57-0.69) with an RCR 0.73 (95% CI = 0.53-0.93) calculated for ≤1 km distance from camera sites. Using CI as an indication of statistical significance, three of the five RCRs were significant and two non-significant. Only one study (DE Germany) gave enough information to calculate the summary statistic percentage crash relative rates ratio (PSRRR), which was 0.44. CI in calculable. In summary, of the 30 RCRs calculated, 13 were significant and 17 were non-significant.

Further details of crash outcomes can be seen in the ‘Characteristics of included studies’ section and in Summary of findings 2 and Summary of findings 3.

Interrupted time series studies

Interrupted time series analyses in this review were reported with both speed and crash outcomes for six countries (AU VIC 1) Phase I and II; state-wide and metropolitan; (ES Barcelona; GB Cambridge; GB Nationwide; NZ Nationwide) with the British Columbia study (CA British Columbia) also reporting some time series data. The statistical analytical method used ranged from simple monthly averages pre and post intervention to more advanced methods like ARIMA or multivariate regression using generalised linear models. Within a study, these analyses were performed for different outcomes and for different constructs or strata. Most studies reported results as estimated percentage changes in the outcome after intervention and the results can be viewed further in Table 3. Times series analysis was also used to analyse the headcount of crash victims. CA British Columbia estimated a drop in crash victims of -31 to -140, while NZ estimated percentage changes in casualties, compared with control, of -19% and -31%. It was noted in AUVIC 1 (Phase 2), the ratio of fatal plus serious crashes to minor crashes (severity), was analysed using a multiplicative model. Significant reductions in crashes were reported (p<0.01) on a log scale linked to increases in traffic infringement notices (TINs) issued and increased publicity, whilst significant reductions in severity were attributable to increases in TINs issued and hours of speed camera operation. Further details for interrupted time series studies can be seen in the ‘characteristics of included studies’ and in Summary of findings 3.

33 Speed cameras for the prevention of road traffic injuries and deaths (Review)  
Copyright © 2010 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.
D I S C U S S I O N

Research conducted to date consistently shows that speed cameras are an effective intervention for reducing road traffic injuries and deaths. The methodological quality of the included studies in this review was at best moderate. Only twelve of the thirty five studies reviewed were categorised as being of high quality (Table 1) in the ‘additional tables’ section. A previous systematic review also noted the ‘weak level of evidence available’ (Pilkington 2005). However it was noted in this review that, in general, some of the more recent studies were conducted with greater methodological rigour.

Whilst randomised controlled trials offer the highest level of evidence, we found no studies using this study design. In an effort to account for local variation, we only included studies in this review that also had control or comparison areas with acceptable before and after study periods. With the exception of studies of short duration, whose outcome focus was the evaluation of speed and/or halo effects, all the included studies collected at least one year of ‘before’ data and one year of ‘after’ data, with fourteen studies having at least two years of ‘before’ data and a follow-up period of at least two years.

Assessment of the quality of non-randomised controlled trials is problematic. After an extensive review of the quality tools available, we decided a modified version of the quality assessment process, as developed by the Cochrane Effective Practice and Organisation of Care Review Group best suited the evaluation of the studies under review. It is well known that the number of potential confounding variables in road safety evaluation studies is very large. Although we looked for how studies controlled or adjusted for any confounding variables, in regards to risk of bias and potential confounders, our main focus was on three variables known to be particularly important in road safety evaluations i.e. regression to the mean, long term trends and changes in traffic volumes (Hauer 1997).

Random fluctuations in recorded number of crashes occur in the long-term. Speed cameras are most frequently introduced at sites based on their more recent history of high rates of speed related crashes. However, it is possible that these crash frequencies were at the high end of naturally occurring random fluctuations, and that in due course crash numbers would regress back to the mean. We checked whether studies had controlled for regression to the mean (RTM) and for those which did not take it into account, we assessed where possible, if it was likely to be an important source of bias. Only ten studies out of a probable twenty four studies, where RTM may have been a sizeable factor, either described and/or controlled for its effects. Some of these ten studies used Empirical Bayes (EB) statistical methods to control for RTM, and this procedure has been suggested as the ideal standard method that future studies should employ (Hauer 2002; Decina 2007). Likewise, only a small number of studies controlled for other long term trends in crash rates and changes in traffic volumes. For example, the examination of possible traffic or crash migration to non-enforced routes is important. This is more likely to occur with fixed overt speed cameras. There is a need for better vehicle exposure/traffic volume data collection over time, so that noteworthy changes can be incorporated when analysing the effects of road safety programs. This is particularly important in light of the fact that studies available in this field have a quasi-experimental design, where the adequacy and appropriateness of comparison/control areas is often questionable. Regarding other possible effects on speed or crashes such as season, time of day, changes in road design, speed limits, and levels of road safety publicity, most studies only controlled for, or described a few of these, if any. No studies provided a rationale for the type of automated enforcement chosen in their particular case. Whilst resource costs are always a consideration, it would enhance the road safety evidence base if studies provided a comprehensive rationale for both the type and number of interventions chosen and their justifications for the length of study and amount of data collected.

We would have liked to have seen much more information on the comparison/control sites to help us judge how well the experimental and control sites were matched. With the exception of a few studies, much of this information was missing. A couple of studies reported that it is difficult, if not impossible, to find matching controls in some places, especially where the use of speed cameras is widespread and in operation for periods greater than ten years. In the United States, where automated speed enforcement is not yet widespread, in contrast to many European countries and Australasia, there is still an opportunity to conduct well-designed studies.

There was considerable heterogeneity across studies involving variations in speed limits, types and duration of interventions, length of follow up periods, setting of interventions, numbers of intervention and control sites and outcome measures. These factors made it difficult to integrate and summarise the evidence. We could not evaluate publication bias due to heterogeneity. However it is reasonable to expect that if any published negative studies existed, they would have received a high degree of publicity, considering the ongoing controversial nature of the debate surrounding speed cameras, in high income countries (Pilkington 2005). In relation to statistical analysis, methods used varied from the application of basic univariate analysis through to more rigorous statistical methodology for interrupted time series data. In some instances authors had developed in-house methods for analysing their data. Furthermore, the way in which results were reported varied extensively across studies, and one of the difficulties we faced was finding the basic information needed to calculate a standardised summary statistic in an effort to compare studies. It is recommended that there be some international consensus as to the expression of outcomes, for example, crash rates per volume of traffic; percentage pre/post changes in speed and percentage pre/post changes relative to controls, all with the accompanying 95% confidence intervals. Until this occurs meta-analysis is not possible. Realistically some heterogeneity will persist across studies as researchers need
Hill 1965

In light of the differences between studies, to critically appraise the results from the 35 studies in this review we examined certain issues which are relevant to making inferences about treatment effects. To this end, we examined the 'signal to noise effect' (Glaziov 2007) and the criteria espoused by Austin Bradford Hill (Hill 1965) to determine the strength of inferences.

The determination of speed camera effect on speed, speeding and crashes is made difficult because traffic volume and speed are not stable but fluctuating, resulting in different degrees of signal to noise on any given road as well as from one road to another. Decreases in average speed, percent speeding and crashes after the introduction of speed cameras were consistently reported across the studies, which strengthens the evidence of a treatment effect. However the magnitude of the effect was variable, ranging from 8% to 70% reductions for speeding over the posted speed limit, 43% to 65% for exceeding the speed limit by 15km/hr or over and 8% to 55% reductions for any type of crash. These are therefore insufficient alone to discriminate signal from noise in the effect. However in this review, in the absence of randomised controlled trials, the inclusion of only controlled before and after studies went some way towards addressing this, by measuring the effect relative to a control situation, as did the inclusion of interrupted time series studies to examine the longer term effect. This was further strengthened by evaluating how the included studies addressed bias attributable to regression to the mean effect.

Austin Bradford Hill (Hill 1965) proposed a list of criteria for strengthening confidence in inferences about treatment effects. The application of these to this speed camera review indicated that all of the studies met the following criteria;

Temporality - speed camera implementation preceded reductions in speed and crashes.

Consistency - all studies, despite different investigations, various times, alternative methodologies, different populations and a variety of geographic settings showed similar results i.e. reductions in speed and crashes.

Theoretical plausibility - the theory that speed camera implementation with associated fines and penalties will result in speed reduction and thus crashes, was a highly plausible explanation.

Coherence - the conclusion ‘made sense’ given the current knowledge about human behaviour and the control of traffic speeds.

Specificity - with regards to the observed reduction in speed and crash outcomes being specifically due to the introduction of speed cameras, the use of control roads or control sections of road, assisted in ruling out other possible causes.

Strength of effect - the strength of intervention, which was examined using the 95% confidence interval for speed and crash based effects relative to control, was inconclusive. This was due to insufficient reporting and lack of data for calculating confidence intervals in most studies.

Dose-response - no studies specifically looked at dose-response relationships in terms of systematically increasing the number of speed cameras and examining this effect on speed or crashes.

Considered together the studies included in this review met the first 4 and arguably 5 of the 7 criteria listed in the Bradford-Hill guide. The results of this systematic review were consistent across all studies, showing that speed cameras do reduce road traffic crashes, as well as those resulting in road injuries and deaths. Whilst this is an important finding, as the prevention of any road injury or death is desirable, we are unable to deduce the overall magnitude or significance of this effect.

Randomised controlled trials (RCTs) are difficult to conduct in road safety enforcement studies. For instance, speed cameras are most often introduced at sites based on their history of high rates of speed related crashes. In these cases it would be considered unethical to randomise intervention to some traffic 'hot-spots' and not to others, especially when the hypothesis is that the intervention will be beneficial. Instead of camera deployment to high crash locations only, it may be worthwhile expanding location criteria, thereby enabling RCTs to be ethically conducted in areas other than high risk. It has been suggested that to realise the full potential safety benefits of speed cameras, wider deployment is needed, taking into consideration less traumatic crashes, as well as fatal and serious crashes, in selecting locations for new cameras. It is argued that camera deployment on sites with large numbers of less serious crashes, would reduce the number of these crash types and perhaps proactively prevent more serious crashes (GB 30mph Roads Nationwide). This proposed expansion however, may require a paradigm shift in public attitudes to speeding, as currently some resentment towards automated enforcement exists and speeding, despite it being a significant factor in road injuries and deaths, remains socially acceptable.

Countries currently considering introducing speed cameras have a unique opportunity to plan the deployment of speed cameras in such a way that it also provides the basis for solid evidence of their effect on speed and crash outcomes. As a result, well-executed RCTs, using matched pairs of camera locations or clusters of camera locations, as well as quasi-experimental research designs such as, controlled before-after trials (using matched location groups) and additionally interrupted time series studies could be conducted. Furthermore, a lengthy pre-deployment stage would be necessary,
with speed and crash data meticulously collected, under pre-spec-
ified transparent guidelines and methodology. Collection needs to
continue in this way during the intervention period and for a
lengthy follow-up period after intervention. However difficult,
there is a need for international standardization of data collection
methods, including standards on how best to collect and measure
speeds and crash data, thus enabling the comparison of studies. A
controlled introduction of speed camera enforcement methods is
important with careful future planning and anticipated outcomes
in mind. In the case of RCTs, a large sampling framework of sim-
ilarly defined ‘lower’ risk sites could be ear-marked for randomi-
sation to the intervention and control arms.

The safety benefits of speed camera enforcement (both mobile
and fixed cameras) reported in this systematic review are consis-
tent with recent reports elsewhere (Elliott 2005; Wegman 2006)
showing consistent reductions in average speeds and proportion
of speeding drivers over the speed limits reflected in reductions in
all crash types, with more marked effects as expected, in the vicinity
of camera sites than in the wider areas. Also consistent with the
former reports, reductions for serious injury crashes and fatalities
are greater than for all other injury crashes, and effects in urban
areas are greater than on rural roads. No sub-group analysis could
be performed in this review to compare in any consistent way,
the effects of fixed cameras versus mobile cameras because of the
considerable heterogeneity alluded to earlier. Whilst the results for
studies with a specific focus on time and distance halo effects all
showed positive effects, results defied comparison because of the
many differences in study periods, number of interventions and
methodology.

One of the associated problems with automated speed enforce-
ment is the tendency for some drivers to brake when passing a
speed camera and then to speed in excess of the speed limit when
out of range of the camera. This behaviour is implicated in some
-crashes. A relatively new method which has the potential to ame-
liorate this, is road section control or average speed check. Unlike
conventional automated speed systems which measure the speed
of a vehicle at one point, section control systems measure the av-
-erage speeds over a distance from at least 500m to several kilo-
-metres. Such a measure can reasonably be expected to have a more
sustained positive behavioural effect and perhaps change the cul-
ture of speeding over a longer time (Goldenbeld 2005). In the
past few years, section control has been introduced in a number of
countries and into the United Kingdom and the Netherlands in
particular, however, assessment of the unfolding technology and
ongoing robust trials are needed to demonstrate the efficacy and
effectiveness of this innovation. All studies meeting the criteria for
inclusion in this review were conducted in high-income countries.
This limits the generalisability of the findings. Middle and low-
-income countries are gradually introducing speed cameras, how-
ever the findings of studies from high-income countries cannot
be assumed to apply to these countries. This presents a unique
research opportunity for these countries to conduct studies, where
the subject of speed cameras is not politicised and yet can be in-
formed by the strengths and weaknesses of the research to date.

Much of road safety research is published in the grey literature.
Every possible effort was made to find all relevant controlled trials,
however unlike medical databases, which include terms describing
the study methodology among its indexing: road safety databases
have a very limited range of indexing terms, which made the iden-
tification of appropriate studies difficult. A need exists for authors
to adequately describe the study design in their reports, and for
editors to demand this, so that improvements in thesaurus terms
-can be made to road safety databases.

Although studies were conducted in varied rural and urban lo-
cations, only a few studies reported on the frequency of injuri-
-ous crashes for different categories of road user (pedestrians, cy-
lists, motorcyclists, vehicle occupants) therefore not enough data
 existed to examine the effect of automated enforcement on road
 trauma by road user category.

The possibility of using speed cameras and associated automated
devices in concert with the developing field of Intelligent Speed
Adaptation (ISA) systems (Carsten 2002) to further enhance road
safety was not within the scope of this current review, but merits
further research.

A sizeable body of literature exists which convincingly dem-
strates the relationship between relative and absolute excess in
speed and road traffic crashes, injuries and deaths. The role for
regulating, monitoring, and enforcing speed limitations is not in
doubt. The principal problem with traditional enforcement sys-
tems is that conventional law enforcement has not been able to
keep pace with increased traffic volumes and increased vehicle
mileage worldwide (Decina 2007). Aberrant speeding behaviour
is widespread and the use of speed cameras and associated auto-
mated devices is considered the most efficient way to significantly
increase both detection and apprehension rates (Zaal 1994). The
main issue then, is establishing that speed camera enforcement re-
duces road traffic crashes, injuries and deaths, as per the findings in
this review. It is speculative whether more intense speed enforce-
ment and higher penalties would be more effective, particularly
for more substantial deviations from the posted speed. However,
the rationale of using speed cameras to impose safe speeds and
limit maximum speeds, for improving road safety is well-founded.

Authors’ Conclusions

Implications for practice

Speed cameras and related automated enforcement devices are a
worthwhile interventions for reducing road traffic injuries and
deaths in both rural and urban settings. Considering continu-
ing increases in traffic volume worldwide, automated enforcement
with speed cameras to curb aberrant speeding behaviour, is a rational intervention to augment or supersede conventional enforcement. Speed cameras used for road section control, which measure average speed over distance, together with related emerging technologies arguably have the potential to favourably influence speeding behaviour and thus enhance road safety.

Implications for research

The results of this systematic review are consistent across studies, showing that speed cameras do reduce road traffic crashes, as well as those resulting in road injuries and deaths. However, in this study, an overall magnitude or significance of this effect could not be deduced because of heterogeneity in background information and road and traffic related factors. An extensive literature exists on issues pertaining to speed cameras. Nonetheless, when searching for studies we found numerous uncontrolled before after studies, many studies without any ‘before’ data and no randomised controlled trials. For the future, interventions using speed cameras and related automatic speed enforcement devices need to be scientifically evaluated using well designed trials, conducted over sufficient time, with several data collection points and controls where possible. These studies also need to clearly show how potential study bias and confounding is controlled, and use standardised study analyses and outcome methodology, so that their true effectiveness can be more accurately assessed. Ideally, this can be more readily achieved if road safety authorities and academic research entities collaborate in the conduct of automated speed enforcement studies through all phases, from program planning to program completion.

ACKNOWLEDGEMENTS

The research reported in this publication is a project of the Centre of National Research on Disability and Rehabilitation Medicine (CONROD) at the School of Medicine, The University of Queensland and supported by the Motor Accident Insurance Commission, Australia.

CHARACTERISTICS OF STUDIES

Characteristics of included studies  [ordered by study ID]

AU NSW 1

| Methods                      | Controlled before-after study.  
|------------------------------| Study period from February 1982 for nine weeks.  
|                              | Speed measurement before, during and after enforcement.  
|                              | Two experimental and one control site.  
| Participants                 | Eastern suburbs of Sydney, two lane sub-arterials carrying less than 10,000 vehicles/day but carrying commuter traffic. Streets had 60 km/h speed limits.  
| Interventions                | Police presence in stationary car with radar units at both sites, overt at site 1 and hidden from view at the primary 2nd site. Primary point for speed measurement was 300m post police car and secondary point was 200m before police car, at both sites. Enforcement periods were 8.00am to 9.00am and 2.00pm to 3.00pm. Speed surveys were conducted between 8.00am to 9.30am and 2.00pm to 3.30pm, i.e. for 30 minutes after police had left the site.  
| Outcomes                     | Effects of enforcement on traffic speeds on urban roads including halo effects.  
|                              | The main finding showed the proportion of vehicles exceeding the speed limit reduced by about 70% when police were present and a time halo effect on commuter traffic lasted at least two days.  
| Notes                        | Perception of enforcement only.  
|                              | Outcomes measured - proportions of speeders over 60 km/h and 70 km/h.  
|                              | Control site characteristics - also had a 60 km/h limit and located in the eastern suburbs. No other ‘control’ characteristics described and authors didn’t describe any other possible confounders.  

AU NSW 2

| Methods                      | Controlled before-after study.  
|------------------------------| ‘Before’ crash data January 1985 to November 1986. ‘After’ crash data January to November 1987. Only 100 km/h speed limit areas within sites used for crash data.  
|                              | Speed data points - before and again at three and six weeks after start of aerial enforcement.  
|                              | Two sites were chosen for detailed examination. Speed was measured at four locations (upstream and downstream as well as within marked area) for each site on four days - one day before aerial enforcement, during, one day after and on the fourth day after operation started.  
|                              | 14 experimental and 14 control sites used for crash analyses and 10 experimental and 5 control sites used for speed analyses.  
| Participants                 | This study reports an investigation of crashes at nine of 24 rural highway sites in New South Wales that came into operation in December 1986. The nine experimental grids provided 14 experimental sites which were matched by 14 control sites.  
|                              | For speed, 10 experimental sites were chosen and five matched control sites were selected. All sites were within a 100 km/h speed limit zones except for two experimental sites and one control site, which were in 110 km/h zones.  

Speed cameras for the prevention of road traffic injuries and deaths (Review)  
Copyright © 2010 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.
Interventions
Aerial surveillance involving a police aircraft flying at 500 to 700m over a series of marked grids on roadways. Speeds were calculated by an observer using a stopwatch and radar unit who timed vehicles over set distances and radioed 'speeder information' to ground crew police in hidden patrol car who then issued speeders with traffic infringement notices.

Outcomes
Reports crash and speed outcomes.
The main finding was a 23% reduction in crashes at experimental sites during the day and a 21% reduction at other times, relative to trends in crashes at control sites.
Reduction in overall mean speed was a small 2-3 km/h. Similar reductions were found at controls sites. While aerial surveillance was operating, speed reductions extending up to 14 km's downstream from the marked zone was evident and some reduction was evident for the day after.

Notes
Experimental (E) and control (C) sites were matched in terms of suitability for aerial surveillance, on average annual daily traffic (E sites averaged 7,200 vehicles per day while C sites averaged 8,000), length (E sites averaged 14.3 km while C sites averaged 16.6 km), road classification (all sites were 2 or 3 lane rural highways) and speed limit (all had a predominant 100 km/h limit).
The possibility of regression to mean regarding the number of crashes at experimental versus control site was discussed. When comparing both crash and speed outcomes, the speed effects were small, however, the speed study was conducted over a short six week period whilst it was noted from the 'crash study' findings, that crash effects were only evident after the program had been in operation a few months.

Methods
Controlled before-after study with a 3 year period of ‘before data’ collection and a 2 year period of ‘after’ data. The overall length of the study was not given.

Participants
Initially, 20 overt fixed camera sites increasing to 28 sites over the course of the study with a total 81 cameras in use. These sites were located in both urban and rural areas and all displayed prominent warning signs.

Interventions
Crash data were collected from the 28 camera sites which were defined as the ‘camera length’; the black length section of road in which the camera was located (1 to 3.3 km in length). Data were also collected for upstream and downstream adjacent sections each typically 1 -2 km’s in length. Speed data were collected from 20 of these sites. Camera sites were matched with 33 controls based on speed limits, number of lanes and types of roads.

Outcomes
The main outcomes at 1 year post showed a 6.3 km/h reduction in mean speeds at cameras sites. At 2 years this reduction was 5.8km/h. For percentage exceeding the speed limit, the reduction was 70% at camera lengths at 1 year and this reduction was maintained at 2 years. There were significant reductions of 86% and 88% along camera lengths at 1 and 2 year's for percentage exceeding speed limits by at least 10 km/h.
For the aggregate changes in crashes, there was a significant 22.8% reduction in all fatal plus injurious crashes at the camera section, a 20.1% significant reduction in injury crashes along the camera lengths and an 89.8% significant reduction in fatal crashes along the camera lengths of road during the 2 years post implementation.

Notes
Sites with high crash numbers were selected for treatment however, no consideration was given to the possibility of biased results due to possible RTM effects. Likewise, no data on control sites were provided in the report and no account was given or adjustment made for other possible confounders. There appeared to be an assumption that traffic volumes remained similar for both experimental and control sites for the whole study period. The study reports increases in speed and crashes at some adjacent non-enforced sites over a 2 year period, which may indicate crash migration occurred.
### AU QLD 1

**Methods**  
Quasi-experimental with comparison group, using trend analysis. Study period 1986 to 1996. Experimental sites have been compared to sites not influenced by the enforcement program. 'Before' data from 1986. Progressive introduction of enforcement program from 1992. 'After' data to end of June 1996.

**Participants**  
Statewide Queensland. State stratified into seven police regions each of which is further divided into urban and rural areas (making 14 strata in total). These areas are further divided into police districts that cover groups of police divisions. Each individual police division (279 police divisions by close of study) select a road segment, typically with 40 sites within it, for enforcement. Speed zones were defined as greater than 60 km/h and zones equal or less than 60 km/h.

**Interventions**  
Stationary marked police car at a randomly selected site for two hours of enforcement between 6.00am and midnight.

**Outcomes**  
Effects of program on crash frequency and crash severity in Queensland (four crash severity levels). Crash data from five years before intervention. All other outcome data come from:  
1. crashes enforced time in enforced area  
2. crashes un-enforced time in enforced area  
3. crashes enforced time in un-enforced area  
4. crashes un-enforced time in un-enforced area  
Estimated 31% reduction in fatal crashes. Overall a significant 11% reduction in total crashes outside of metropolitan Brisbane.

**Notes**  
This study of Random Road Watch (RRW) is a traffic policing program in operation in Queensland, Australia. It differs from other road safety enforcement programs in that an explicit resource management technique is used which randomly schedules low levels of police enforcement with the intention of providing long-term widespread coverage of a road network. Outcome crash data from police records rather than an automated system. Characteristics of comparison sites given.

### AU QLD 2

**Methods**  
Controlled before-after study. Study conducted from May 1997 to end of June 2001. 'Before' data from January 1992 to December 1996. Experimental areas within 6km of camera site dissected by three (0 to <2km, 2 to <4 km, 4 to <6km). Matched control areas outside the 6 km “zones of influence”. Crash data from January 1992 to June 2001.

**Participants**  
Sites throughout Queensland that had undergone a speed limit review and had a high speed related injurious crash history.  
500 sites in 1997 to over 2,500 sites by June 2001.

**Interventions**  
Mobile overt cameras used which were randomly deployed and operated for up to six hours per day at one or more of three sites per day.

**Outcomes**  
Localised crash effects were measured. Greatest reductions in injury and fatal crashes within 2 km of cameras. A 45% reduction in fatal crashes in areas within 2 km of camera sites. Corresponding reductions of 31%, 39%, 19% and 21% were estimated for hospitalisation, medically treated, other injury and non-injury crashes respectively. This
equates to an annual crash reduction of 110 fatal, 1100 hospitalisation, 2200 medically treated, 500 other injury and 1600 non-injury crashes in Queensland. For the total post intervention period between January 1997 and June 2001, the aggregate changes in crashes was a significant reduction of 17.5% in all severity crashes within 2 km of cameras, a 11.4% reduction in all severity crashes in the 2-4 km zones and a 10.7% reduction in the 4 to 6 km zone. Significant reductions in no injury crashes were also recorded at 2 to 4 km and 4 to 6 km zones.

### Notes
Control sites matched by level of urbanisation, similarity of police region and similarity of Random Road Watch (RRW) program.
A study limitation was the observation that, crash to nearest camera site didn’t necessarily mean that a camera was there at the time. Adjustment was not considered for possible regression to the mean effects.

### AU South Australia

#### Methods
Controlled before-after study.
'After' speed data (measurement x 4) from March 1992 to February 1993.
Ten experimental sites and two control sites.

#### Participants
Residential area with ten deployment sites (streets) in city of Unley, South Australia approximately 4km from north to south and 700m from east to west.

#### Interventions
Overt mobile speed camera, random deployment to enforce a new 40 km speed limit to local residential streets.
Low intensity enforcement.
(1.5 hours per fortnight) began March 1992. High intensity enforcement began October 1992 (at least 1.5 hours x 5 per fortnight).
Operational conditions for control sites not clearly described.

#### Outcomes
Median traffic speeds reduced sharply by 5 km/h on experimental roads after program launch and reduced very little thereafter despite intensified enforcement, however improvement sustained over the whole trial period whereas control sites showed no change or slight increases in speed.

#### Notes
Controls were matched on the basis of width, length and traffic flow. Assumption that speed limit same for experimental and control streets as they were adjacent.
Speed data on all vehicles passing each study site (experimental and control) was collected for one full week during each survey.
Both speed and traffic volumes were recorded using Golden river classifiers with amphotometer tubes as sensors. This equipment was capable of storing a complete week's data, it achieved this by 'binning' data i.e. instead of recording each vehicle's speed, it simply recorded the passage of a vehicle in a particular speed category which imposed some restrictions on data analysis.
### AU Tasmania

**Methods**
Controlled before-after study.
Total study length was two years between December 1984 and December 1986.
Continuous speed measurement for periods of three days to two weeks in one month in 1984, 1985, 1986.
Crash data from 1979 to 1986.
Three experimental sites and one control site plus all other Tasmanian roads also used for crash comparisons.

**Participants**
Three road locations each 12 km to 16 km in length divided into approximately 1 km sections.
Road type - contiguous sections of rural highway or main road where speed limit was 110 km/h. Control was similar road within 10 km of experimental sites.

**Interventions**
Overt stationary police vehicles for 4 by 2 hours periods 7 days per week, random scheduling of road sections, 5 site visits per week for 2 weeks then 2 to 3 site visits thereafter.

**Outcomes**
A significant decrease in mean speeds by average of 3.6 km/h (p=0.01) compared to before, but reduction only maintained during enforcement showing no time halo effect.
A significant 58% reduction in serious injury crashes (admitted to hospital or fatal) compared to previous crash history and crash occurrence on other rural roads.
In non-enforced times of day a 33% increase in major injury crashes was seen.

**Notes**
Characteristics of trial site lead it to be classified 90 km/h, whilst control site was 110 km/h, thus lower mean speeds at trial site. This was taken into account in the analysis and discussion.

### AU VIC 1

**Methods**
Interrupted time series design with a control arm for phase 1 and phase 2 of a 5-phase study.
Total study period 1983 to 1993.

**Participants**
Statewide Victoria inclusive of rural and metropolitan areas. Metropolitan areas defined as those areas within specified police districts.

**Interventions**
Interventions were:
1. mobile radar devices
2. hand held laser speed detector devices
3. speed cameras - progressive introduction of 54 speed cameras between December 1989 to January 1991 with 4 distinct points (T1a, T1b, T2a, T2b). Initially speed cameras were overt then from 1990, largely covert.

**Outcomes**
Phase 1 - General effects; effect of speed camera program on crash rate and severity covering first 12 month post intervention period, December 1989 to December 1990.
Phase 2 - Impact of program mechanisms i.e. number of traffic infringement notices (TINs), hours of speed camera operations, amount of paid TV publicity, demerit points in relation to injury crash incidence and severity during low alcohol times of the week across the first two year post intervention period.
Phase 3 - Areas and times of operation of speed camera program affecting frequency and severity of all types of injury crashes during both high and low alcohol hours in Melbourne covering 18 months of program (July 1, 1990 to December 31, 1991).
Phase 4 - Program effects on speeds, including influence of publicity from sample sites between November 1989 to June 1991 (five measurements) and from continuous sites November 1989 to January 1992 (monthly measurements for one week duration).
Phase 5 - builds on phase 3 by analysing localised effects of program in; a) rural towns and rural highways B)
### AU VIC 1 (Continued)

<table>
<thead>
<tr>
<th>Notes</th>
<th>Only results from phase 1 and 2 of this 5-phase study were reported and tabulated, as phases 3, 4 and 5 did not have before and after data. Control area for phase 1 and 2 was another State, New South Wales, as no suitable control in the State of Victoria, thus some limitations, however most comparable in terms of urbanisation, economic activity, population size, vehicle kilometres travelled and unemployment rate. Controlled for random breath test (RBT) program in operation, by restricting relevant crash analysis to low alcohol hours.</th>
</tr>
</thead>
</table>

### AU VIC 2

<table>
<thead>
<tr>
<th>Methods</th>
<th>Controlled before-after study. Study period May 2000 to October 2000, a period of about 20 weeks. 'Before' period 8th May 2000 to 21st May 2000. 'After' period 18th October to 31st October 2000. 1 experimental and 1 control site.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>Domain tunnel Melbourne, three-lane urban road with 80 km/h speed limit. The control was a second three-lane road upstream of the tunnel.</td>
</tr>
<tr>
<td>Interventions</td>
<td>Fixed position speed camera operating continuously.</td>
</tr>
<tr>
<td>Outcomes</td>
<td>Net 3.4% speed reduction (after consideration of changes in average speeds that occurred at control site during the same before-after periods). The proportion of drivers exceeding the 80km/h posted speed limit decreased by a net 66%. For drivers speeding over 90km/h, a net 79% reduction was seen, and for those over 110km/h, a net 76% reduction was reported. Estimated 13% reduction in fatal crashes, 10% reduction in serious injury and 7% reduction in overall injuries.</td>
</tr>
<tr>
<td>Notes</td>
<td>The 'before' period is when the cameras are in the tunnel but no infringement notices are being issued, therefore arguably not truly independent as not everyone would know the cameras weren't operational. This would probably have the effect of slowing down speed in the before period making differences smaller.</td>
</tr>
</tbody>
</table>

### AU VIC 3

<table>
<thead>
<tr>
<th>Methods</th>
<th>Controlled before-after study. Study period 1992 to 1997. 'Before' crash data July 1992 to June 1994. 'After' crash data July 1995 to June 1997. Experimental sites were undivided roads in 100km/h speed zones. Control sites were defined as undivided roads in 100km/h speed zones when mobile radar was not present within four days prior to a crash.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>Mainly rural Victoria with some enforcement (about 10% of total mobile enforcement activity) in the outer Melbourne police districts of Victoria.</td>
</tr>
</tbody>
</table>
Interventions were overt patrol cars using mobile radar, covert patrol cars using mobile radar, and mixed overt/covert cars using mobile radar. Most operations were overt. Intervention events were divided into Period A (July 1995 to June 1996) when 48 radars were in operation and Period B (July 1996 to June 1997) when 73 radars were in operation and Period A+B (July 1995 to June 1997) when up to 73 radars were in operation.

Outcomes were reductions in injury crashes within four days of camera enforcement and during July 1995 to July 1997. A net reduction of 71.3% (P=0.064) was found for injury crashes occurring on the same day or up to four days after the enforcement was present. The effect was strongest (a net 73.9% reduction (P=0.045)) on the day when a mix of overt/covert enforcement was in use.

The study compared crashes that occurred during the period of mobile radar enforcement with the period when there was no mobile radar enforcement, however the authors state that other types of enforcement e.g. hand held radars may have been operating on the same roads during the pre-period that may not have been accounted for by changes in the control crashes. Calculation of net percentage change between control and experimental groups was designed to control for other confounders. The analysis assumed that crashes were exclusively influenced by the most recent mobile radar enforcement present in a particular region. This most recent enforcement was considered to override any enforcement that occurred one to four days earlier, which also may have influenced crash rate. Given that a four day residual effect on crashes was found in the analysis, the study authors acknowledge the most recent enforcement may not necessarily have been the most important in influencing crash frequency.

### CA British Columbia

#### Methods
Controlled before-after study.

#### Participants
Province-wide throughout British Columbia.
Controls consisted of 19 sites on selected highways and streets where radar was not operating. Data was collected by induction loops from these sites between September 1995 and November 1996.
Eight days of speed data collected every month.

#### Interventions
30 mobile speed cameras using unmarked mini-vans.
30,000 hours of operation recorded in first year with about 250,000 tickets issued.
Intervention period was August 1996 to July 1997.

#### Outcomes
Proportion of speeding vehicles in May 1996 (before) at photo radar sites was 66%. By July 1997(after) it was about 35%. At control sites speeding vehicles in September 1995 was ~73%. In Nov 1996 it was ~61%.
Approximately 25% reduction in crashes to that expected. A significant 11% reduction in number of victims with an average decrease of 139 daytime traffic crashes requiring an ambulance.
A 17% reduction in daytime crash fatalities.

#### Notes
Selection criteria for control sites included distance to traffic control devices, non-congestion, speed limits but how well they matched experimental sites not discussed.
Controlled for vehicle miles travelled (motor fuel sales) state of the economy (unemployment rate) and amount of...
drink driving (draught beer sales) in modelling. Later beer sales and unemployment rate excluded from time series models. As the total number of speed related crashes were the main focus of this study for the whole of the province, regression to the mean is an unlikely confounder as are spill-over effects.

### CA Toronto

| Methods       | Controlled before-after study.  
|               | Study period October 1979 to December 1979; five week study.  
|               | Data collection by 2.5 hours per day on weekdays over the five consecutive weeks at four experimental and four control sites. |
| Participants  | Locations were semi-rural, two-lane roads west of metropolitan Toronto. |
| Interventions | Four experiments are described, each experiment consisted of measuring speed of vehicles before, during and after enforcement took place. The four experiments differed in the number of days of enforcement. Each of the four experimental sites had an 'upstream' enforcement and a 'downstream' measurement site (latter was 1 to 2.5km from the site of enforcement).  
|               | In experiment 1 the police van was visible in advance.  
|               | In experiment 2 to 4 the police vehicle was visible to the driver only 200m to 300m before passing the speed sensors. |
| Outcomes      | For a single application of enforcement a 'time halo' lasted for up to three days.  
|               | When enforcement was applied for five consecutive days, a time halo of at least six days from the last day of enforcement was found.  
|               | When enforcement was in place the average speed of the traffic stream was reduced at the site of enforcement, upstream and downstream of it.  
|               | At the site of speed limit enforcement, the average speed of the traffic stream was around the posted speed limit.  
|               | This reduction in average speed decays exponentially with distance downstream. |
| Notes         | Study authors state control sites were selected to take "account of the effect of weather, day of week and other factors". They also state concurrent measurements were done on control roads, otherwise no further description of control characteristics were given or how close control sites were to experiment sites.  
|               | Little information only on 'before' data. |

### CA Vancouver B.C.

| Methods       | Controlled before-after study.  
|               | Two years 'before' crash data from April 1994 to March 1996.  
|               | Two years 'after' data from April 1996 to March 1998. |
| Participants  | One 22km four-lane highway corridor in rural/semi-rural countryside in province of British Columbia. Controls consisted of other selected highways and streets where radar was not operating, used for crash comparisons. No true control for speed (see notes). |
### CA Vancouver B.C.

**Interventions**

12 individual photo radar locations along corridor (not active at the same time). Study corridor was divided into photo-radar influence (PRP) locations and non-photo radar influence (non-PRP) locations. A PRP location was designated as a 2km section of highway, 1 km in each direction from the photo radar enforcement. The non-PRP locations varied in length from 0.4 to 5.9km, depending on the proximity to the adjacent treatment locations.

**Outcomes**

2.8km/h reduction in mean speed at monitoring site 2km from treatment area. A 14% (+/-11%) reduction in expected crashes at PRP locations, a 19% (+/-10%) reduction at non-PRP locations and a 16% (+/-7%) reduction along the study corridor as a whole.

**Notes**

Site specific study using data from the same period as the province wide study. PRP and non PRP areas cannot be considered independent of each other as in some cases the non-influence areas only 400m long and are in between PRP areas. Results suggest this lack of independence too. Speed data was captured at PRP locations by the photo radar device but only when radar operating. Speed captured at the monitoring site (2km south of the nearest photo radar) on a 24 hour basis collected over an 8-day period every month by induction loop for both the before and after period. Controlled for regression to mean.

### DE Germany

**Methods**

**Participants**

One interstate road (A3) on the autobahn at Elzer mountain in Germany. The rest of the same autobahn used as the comparison. Speed limits of 100km/h for car lanes and 40km/h for truck lane.

**Interventions**

Overt speed cameras by three in fixed position on bridges (corresponding to three lanes on autobahn) operating continuously. Police surveillance also in operation several times per year. Speed limits of 100km/hr for cars and 40km/hr for trucks.

**Outcomes**

In 1971 before enforcement the median speed was 137km/h and 122km /h in the left and middle car lane. By 1981 the median speed was 97km/h and 94km/h in these lanes. The 85th percentile speed reduced from 150km/h and 135km/h in the left and middle lanes in 1971 to 108km/h and 98 km/h respectively by 1981. Reductions in median and 85th percentile speed also occurred in the truck lane, with median speed down from 55km/h to 32km/h between 1971 and 1981 and 85th percentile speed down from 80km/h to 41km/h in the same timeframe. Personal injury crash frequency reduced by a ratio of 18:1 between 1971 and 1981. Reduction in crashes from 200 in 1970-1971 to 84 in 1973 to about 27 in 1980 for the most dangerous downgrade section. Fatalities reduced from eight in 1970 to 1971 to three in 1973 to an average of one per year since 1976. Personal injury crashes reduced from about 82 per year in 1970 to 1971 to 27 in 1973 to about seven per year since 1976.

**Notes**

Speed measures in the before period relate to speeds before a) introduction of speed limits and b) introduction of speed cameras. Summary statistics not given. Not clear if the analyses controlled for any known or potential confounders.
**DK Denmark**

<th>Interrupted time series study. The study period was January 1, 2001 to March 31, 2005, consisting of a 2 year 'before' period January 1, 2001 to March 31, 2003 and an 'after' period April 1, 2003 to March 31, 2005.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>A 24.1 km experimental urban beltway which had 3 lanes in each direction, with posted speeds of mainly 80 km/h. The remaining sections had posted speeds of 60 km/h. The treatment section had no traffic lights.</td>
</tr>
<tr>
<td>Interventions</td>
<td>8 overt cameras operated from 22 different sites. The cameras were moved randomly from site to site during the study period.</td>
</tr>
<tr>
<td>Outcomes</td>
<td>The outcome measures were numbers of road crashes, numbers of people injured (combined fatal and non-fatal) and number of vehicles involved in crashes. The relative risk of a road crash on weekdays after 2 years post implementation was 0.69 (95% CI = 0.54 - 0.89) with the relative risk of injury 0.70 (95% CI = 0.53-0.92). No change of note was seen at the comparison sites. Attributable fraction estimates for the 2 years of the speed camera intervention showed 364 crashes prevented, 507 fewer people injured and 789 fewer vehicles involved in crashes. After controlling for trends and seasonality there was an estimated 26% reduction in total crashes with a similar 27% reduction in the number of injury crashes.</td>
</tr>
<tr>
<td>Notes</td>
<td>Comparison sites were used in this study, however these sites were significantly different from experimental sites in that, they consisted of arterial roads with traffic lights, posted speeds of 50 km/h and 2 to 4 lanes. Furthermore, random mobile cameras operated on these roads from time to time. The study controlled for general trends and seasonality and discussed crash migration, time of day and traffic flow but did not account for RTM effects.</td>
</tr>
</tbody>
</table>
### FI Finland

**Methods**  
Controlled before-after study.  
Study period April 1990 to December 1993.  

**Participants**  
Experimental area was a 50km length of a two-lane stretch of highway No. 1, leading west of Helsinki.  
Control area was Highway No 6 leading east of Helsinki.  
Speed limits of 80km/h and 100 km/h on study sites.

**Interventions**  
12 fixed camera poles distanced between 1.5km and 7km.  
One direction of road monitored and camera rotated randomly between poles.  
Duration of surveillance 8 to 36 hours, involving 8065 hours of operation between April 1st 1992 and December 31st 1993.

**Outcomes**  
On 80 km/h sections an 8% reduction of speeding vehicles seen on experimental sites compared to control sites in year one, with a further 2% decrease in year two.  
On 100km/h stretches a 5% reduction in number of speeders was seen in year one, with a further 2% reduction in year two.  
Distance halo of 3km upstream and 2km downstream.  
A non-significant 19% reduction in crashes (not defined) compared to controls.

**Notes**  
Crash analysis is limited as only a short follow-up period for crash data (April 1992 to December 1993).  
Control site characteristics apart from road type and speed limits not given. Study doesn't account for any other potential confounders either.

### GB 30mph Roads Nationwide

**Methods**  
Before/after study which used U.K. national crash totals and traffic flows as a comparison group for analysis of crash effects. Speed effects were based on before/after observations with the 'before' data simply compared to the national average for cars on 30 mph roads. The study period varied depending on time of implementation across sites. Exact start and finish dates were not given, however for crashes the 'before' period consisted of 3 years of data collection at each site prior to program implementation and the 'after' period was an average 2.3 years and up to 3 years post implementation for each site. Length of study period for speed was not described.

**Participants**  
62 experimental sites on roads, all with a 30 mph speed limit in various locations throughout the UK, all with reported severe speeding problems.

**Interventions**  
Fixed overt cameras, which included warning signs. Crash data were collected for all crashes occurring up to 1km either side of the cameras.

**Outcomes**  
The outcomes measured for speed were mean speeds, 85th percentile speeds and percentage exceeding the 30 mph speed limit. Mean speeds were reduced by an average of 4.4 mph and 85th percentile speeds by 5.9 mph. There was also a 35% reduction in the percentage exceeding the speed limit. The reduction in all speed measures was statistically significant at the 5% level. The outcomes measured for crashes were personal injury crashes at various distance from the enforcement site as well as fatal and severe injury crashes. Separate crash outcome estimates are given for the effects of traffic flow and crash migration as well as for changes in general crash trends and RTM.  
For personal injury crashes (PIA's) the observed effect for up to the 500m distance, was a 36% (-51 to -11 95%CI) reduction in fatal and serious crashes. After adjusting for trend, the outcome translated to a 30% reduction in all PIA's with a 29% reduction in all fatal and serious crashes up to the...
500m distance. Estimates of changes in crashes attributable to RTM effects showed a reduction for both types of crashes at all distances up to 1km. The RTM effect varied from a -4% for personal injury crashes to a reduction of -18% for fatal and serious crashes. The latter accounted for over half of the overall observed decrease in fatal and serious crashes for 500m monitoring length. After accounting for all potential confounders including changes in speed and traffic flow, the overall average effect of speed cameras on crashes was a reduction of 25% in PIAs and an average 11% reduction in fatal and serious crashes for the 500m monitoring length, with a similar average 24% reduction in PIAs and 13% reduction in fatal and serious crashes at the 1km length.

Notes

The analyses included UK national crash totals and traffic flow for comparative purposes. Empirical Bayes methods were used to control for RTM, crash changes attributable to changes in traffic flow, speed behaviour and crash trends were taken into account.

The estimate of crash trend effects showed a conflicting average increase for personal injuries due to trend and an average decrease for fatal and serious crashes. The authors state this is a consequence of the range of implementation dates for the 62 camera sites, and that one needs to consider whilst the underlying trend is downwards for all crashes, total personal injury crashes tend to fluctuate with several year on year increases before declining again, whereas fatal and serious injuries tend to decline more consistently. Hence results need to be considered in light of implementation dates.

Main outcome was a fall in personal injury crashes of 25%, with 20% of this fall attributable to program impact on speed and 5% due to changes in traffic flow i.e. traffic migration.

GB Cambridge

Methods

Interrupted time series design.
Study period 1990 to 2002.

Participants

Drivers of motorised vehicles on designated roads in Cambridgeshire. Roads included major A roads, urban and trunk roads.
Injury crash data collected over a 12 year period 1990-2002 for camera and non-camera sites. Speed data from before and after installation of cameras as well as limited data from surrounding areas during the same period plus rest of network comparison.

Interventions

Progressive introduction of speed cameras from 1991 consisting of 49 overt fixed camera sites with warning signs within 1 km of camera site. Some roads had multi-camera and other stand-alone sites. Both before and after periods varied depending on implementation date. Minimum length of before period not documented. Minimum length of after period was one year.

Outcomes

Outcome measures were injury crashes weighted according to the expected frequencies for each crash severity type. Time dependent coefficients were derived using all crashes in Cambridgeshire to control for RTM and time trends. Mean crash count per month at camera sites weighted by severity. Estimates in crash count for different distances from camera sites.
A 45.74% reduction in weighted injury crashes within 250m from camera sites (total monthly before count of 23.4 compared to total monthly after count of 12.7) with lesser but still significant decreases observed in the wider surrounding areas such as a 20.86% reduction inside a 2000m radius from the camera. Authors concluded from the analysis of different road types that the greatest reduction in crash numbers is got from roads with the highest number of speeding offences.
GB Cambridge  
(Continued)

Notes  
Extension of earlier study. Hypothecation introduced in 2000. As crash rates near camera sites reduced most, authors argue that sudden braking near camera sites is not increasing crash numbers. They also argue that little evidence exists for accident migration based on looking at the results of crash reductions at different distances from the camera sites. Authors do not provide data to show how effective their efforts were for controlling other potential confounders in this study.

GB Nationwide

Methods  
A before after study using two types of comparison groups, one consisting of sites within the partnership areas with no camera intervention and the other using crash data acquired from each police force across the U.K. not within the partnership area. (these non-partnership areas may have had their own camera enforcement, which were not part of the cost recovery program)

Study period varied with incremental implementation of program. Scope of 4 year report covered the period April 2000 to March 2004. By the end of the study period 38 partnership regions across the United Kingdom, under the national cost recovery program, were involved.

Over 20,000 speed surveys taken over 4 years from across each partnership area. Before speed data period had variable timeframe from prior to the introduction of speed cameras or from pre-existing camera sites (before becoming part of the cost recovery program) 'After' speed data between 2002 and 2004. Trends in speed at fixed camera sites (89 sites) with at least 5 'after' speed readings plus trends at mobile camera sites (63 sites) were evaluated. The crash ‘before’ data consisted of at least 3 years baseline and the ‘after’ data was collected monthly for periods of at least one year.

Participants  
38 partnership areas in both urban and rural locations throughout UK, involving multiple road types and speed limits.

Interventions  
- Fixed cameras, consisting of standard fixed cameras installed in camera housings or fixed cameras at specified distances (used to calculate "time over distance" to provide average camera to camera speed, based on the distance between the fixed cameras divided by the time taken to travel) All fixed cameras became overt following guidelines introduced in June 2002.
- Manned overt mobile speed cameras.
- Red lights cameras (mainly in urban areas).

Outcomes  
Speed outcomes measured: Mean speed, 85th percentile speed, percentage of vehicles over the speed limit and percentage exceeding the speed limit by more than 15mph. Speed results across all new camera sites included a 2.3mph reduction (6% reduction) in mean speed, 3.1mph reduction (7% reduction) in 85th percentile speed, 30% reduction in vehicles exceeding the speed limit and a 43% reduction in vehicles exceeding the speed limit by more than 15 mph. Time over distance cameras were shown to be particularly effective (around 100% reduction) at reducing speeds exceeding 15mph over the speed limit. In general the greatest reduction in speed (in absolute and percentage terms) against all 4 outcome measures was found at urban fixed speed camera sites. The least reduction in speed was found at rural mobile camera sites.

Crash outcomes measured: Killed and seriously injured (KSI's) and personal injury crashes (PIC's).

Across all sites KSI's decreased by 42%. This equated to about 1700 fewer KSI's per annum at these camera sites. Fixed cameras in both urban (47% reduction) and rural areas (62% reduction) were more effective than mobile camera sites in urban (35% reduction) and rural areas (34% reduction) at reducing KSI's. Across all sites PIC's decreased by 22%. This equated to a reduction in PIC's of about 4200 at camera sites. Overall fixed sites were slightly more effective at reducing PIC's (-24%) when compared to mobile sites (-21%). Fixed camera sites in rural locations were the most effective combination at reducing PIC's (-33%) however across all sites, 85% of the reduction in PIC's was in urban areas. Crash results are consistent with speed analysis in that, fixed cameras were shown to be more effective than mobile cameras.
GB Nationwide (Continued)

Notes
Crash analysis accounted for speed limits, seasonality and time trends. Authors argue because no significant difference was found between fixed and red light cameras they were grouped together in the analysis as fixed cameras, however effects may be different for both camera types. Study controlled for seasonal effects and long term trend by using a general comparison group from all of the U.K. using data from areas other than the study and by comparing relative changes in injury crashes to national trends. Did not discuss potential impacts of these factors. No discussion regarding traffic volumes before and after implementation or how comparison sites matched regarding traffic flow. No discussion regarding possible crash migration effects resulting from the enforcement program. The effects of regression to the mean RTM, were considered using an empirical Bayes approach for a small sub-set of sites only. This sub-set was not representative of all camera sites nationally, consisting only of single carriageway urban roads with mainly 30 mph speed limits. Authors argue that RTM bias was not a factor because the number of crashes was not the sole criterion for site selection.

GB Norfolk

Methods
Controlled before-after study. Study period October 1, 1999 to September 30, 2003 providing 24 months pre and 24 months post camera operation crash data.

Participants
29 experimental sites consisting of a 72 km total road length, most with posted speeds of 60 mph or above. Typically sections of enforced roadway were about 3 km in length, although road configuration and safety considerations meant that lengths varied and mobile camera units might just operate at 1 or 2 specific points within each designated road length. The authors state that no suitable controls could be found for 10 of the experimental sites. The remaining 20 experimental sites were compared with between 12 and 44 control sites.

Interventions
Mobile overt cameras at 29 sites. Deployment was mainly rural with just 2 urban experimental sites. Control sites were chosen on the basis of similar road class, road length and speed limit as experimental sites. They were also matched either on number of minor road junctions or on traffic flow averages.

Outcomes
At camera sites there was a reduction of 19% for all crashes and a reduction of 44% for fatal and serious crashes. The authors state that the reduction in total crashes was significantly greater than that expected from the effect of regression to the mean in 12 out of the 20 experimental sites tested.

Notes
Account was taken of RTM effects, crash migration, crash severity trends and possible road engineering events.

GB South Wales

Methods
Controlled before-after study. Study period 1996 to 2000. Average length of time before intervention was 38 months and average follow-up was 17 months. Crash data (with at least one injury) for period 1996 to 2000.

Participants
101 experimental sites, all types of roads in South Wales, UK with matching control sites from Gwent, a neighbouring police force area.

Interventions
Mobile overt speed cameras, 12 cameras by end of 2000.

Outcomes
Rate ratio of injury crashes at intervention and control sites (0-500m route). A reduction of 50% in personal injury crashes which was sustained for two years after the intervention.
### GB South Wales

**Notes**
Study compared various methods, circles and routes of various sizes to assess the local effectiveness of mobile speed cameras, and then used the most appropriate method found to examine speed cameras by time after intervention, time of day, speed limit, and type of road user injured.

Methodology not clear in this study.
Control sites matched for posted speed limit, road class and injury crash history.

---

### GB West London

**Methods**
Controlled before-after study.
Study period 1989 to 1995.
Three year 'before' period October 1989 to October 1992.
Three year 'after' period October 1992 to October 1995.

**Participants**
Trunk and non-trunk A class roads in London. Trunk road network was 85km in length.
Controls were comparable roads in other areas of London with no cameras over the same period.

**Interventions**
21 fixed speed camera sites at start of project in 1992 (plus 12 red light camera sites) along 10 routes.

**Outcomes**
Significant reduction in crashes, fatal, serious injuries and lesser injuries per se and in relation to controls.
Greatest improvement in higher severity crash outcomes.
A reduction of 12.4% for all crashes.
Fatal crashes reduced by 69.4% (62 down to 19) relative to before and a significant 55.7% relative to controls.
Serious injuries reduced by more than 25% from 4983 to 4375, resulting in a 31% reduction in fatal and serious crashes combined.
A reduction of 7.9% in slight injury crashes was reported.

**Notes**
No separation of effects of red light versus speed cameras.
Part control for crash trends. No control for other potential confounders.

---

### HK Hong Kong

**Methods**
Controlled before-after study.
Study period 1998 to 2000, a period of two years.
'After' period from January 1999 to January 2000.

**Participants**
The experimental group was one 20 km section of highway in Hong Kong divided into 2km sections.
The control group was other highway sections in Hong Kong where no speed camera enforcement took place.

**Interventions**
10 fixed speed enforcement systems with two cameras operating continuously on a rotational basis (1:5).

**Outcomes**
65% reduction in cars travelling in excess of 15 km/h or more over the speed limit.
23% reduction in number of injury crashes compared to before period. In same period there was a 32% increase in number of injury crashes in the control group.
Fatal crashes reduced by 66% in the experimental group.
| Notes | No detail on characteristics of control group given.  
|       | Traffic conditions and road type discussed in relation to speed camera operation but not in relation to potential confounding.  
|       | Statistical methods not adequately shown.  
|       | Study limitations not discussed. |

### NL Friesland

#### Methods
Controlled before-after study. Study period 1990 to 2002 in total, with an 8 year ‘before’ and a 5 year ‘after’ period for crashes. For speed, the study time was a 1 year ‘before’ and a 5 year ‘after’ period. Initially enforcement of 8 police regions occurred in 1998 and by January 2001, program implementation had occurred in all 25 police regions.

#### Participants
Motorised vehicles on rural 80km/h and 100 km/h single carriageway roads, with a police reported high injury crash rate, in the before period of 1992 -1996. A total of 28 road sections, with a total length of 116 km with high injury crashes were subject to targeted enforcement.

#### Interventions
The enforcement involved the use of covert, mainly mobile cameras. An average of 1 -2 hours of enforcement per site per week was implemented. For the first 3 years, deployment was around 4000 -5500 operational hours, increasing to over 14,000 hours in the 4th and 5th year. Monitoring of speed was used to re-distribute enforcement amount. For speed effects, the treatment group involved 12 road sections with a total length of 60 km/h and speed limits of 80 km/h. The control group was 15 comparable rural road sections within the province of Friesland, with a total length of 51km and speed limits of 80 km/h. For crashes, the treatment group involved all 28 speed camera enforced rural road sections, 23 of which, had speed limits of 80 km/h and 5 had speed limits of 100km/h. The control group were all other non-enforced rural roads in Friesland, approximately 5200 km in total length.

#### Outcomes
Speed outcomes were annual mean speeds per road section and annual percentage of speeders over the targeted speed limit. The results were a non-significant mean speed reduction of 4 km/h on the enforced roads and a 1.5km/h reduction on the control roads between 1997 and 2002. The percentage of speeders decreased by 12% on the treatment roads compared to 5% decrease on the control road sections. Greatest reductions in mean speeds and percentage of speeders occurred at the start of the enforcement program and again in 2001 when enforcement was intensified. Regarding crashes, odds ratios for injury accidents (all severities) was 0.79 ( 0.66-0.95) showing a 21% reduction for the enforcement period compared to the before period on the enforced sections of roads. The odds ratio for serious traffic casualties (fatalities plus hospital admissions) was also 0.79 ( 0.63-0.99).

#### Notes
Each enforced road had a posted road sign warning that stated speed camera enforcement was possible. This sign was constantly present, independent of the actual presence of enforcement. Regarding speed effects, the control group had much lower traffic volumes compared to the treatment group (3800 versus 7200 vehicles per hour in 1997) . According to the authors the odds ratios for crashes was estimated, based on relatively small numbers. Extensive weekly media coverage and a dedicated publicity officer were used for a public information and education campaign. This factor plus RTM and program spillover effects were among possible confounders. However, authors argue RTM was unlikely to be an issue because crash rate had remained similar for 8 years.
### NL Netherlands

**Methods**  
Controlled before-after study.  
Main study conducted October 1990 to June 1991 using four experimental and four control roads for phase 1 and phase 2 study.  
Then phase 3 of Netherlands study conducted in September 1994, with two ‘new’ control roads for crash data comparisons.

**Participants**  
Four two-lane rural road stretches in four Dutch provinces, 10-17km in length.  
For phase 3, one road of main study, the N266 in the province of Noord-Brabant used.

**Interventions**  
Unattended fixed overt speed cameras and radar operating randomly off three or four posts installed along each of the four experimental roads from early morning until midnight. Phase 3 continuing from phase 2 also used fixed overt speed cameras and radar.

**Outcomes**  
Speed and crash outcomes.  
Aggregation of data from the four roads (compared to phase 0) showed a reduction in average speed of 3km/h in phase 1 and 5km/h in phase 2, a reduction in 85 percentile speed of 3km/h in phase 1 and 8km/h in phase 2. A reduction in proportion of speeders from 38.2% to 28% in phase 1 and from 38.2% in phase 1 to 11.4% in phase 2.  
A reduction of 35% in the total number of crashes for phase 1 and 2 compared to same period three years previously and compared to the control roads (in phase 3).  
Speed and crash reductions achieved in original study were maintained three years later.

**Notes**  
For phase 3 crash data on experimental road compared to 2 control roads.  
No control arm used for speed comparisons.

### NO Nationwide

**Methods**  
Controlled before-after study.  
Study period 1988 to 1993.  
Mean length of ‘before’ period was 3.94 years.  
Mean length of ‘after’ period was 4.61 years.

In no case before or after period less than one year.

**Participants**  
64 road sections each 1-2km long of a total 336.3km road network. All roads rural and two-lane in Norway where automatic speed enforcement had been introduced by 1995. Photo radar enforcement began in 1988.  
The total number of crashes in the rest of the country in the before and after period was used as a comparison group.

**Interventions**  
Fixed overt speed cameras.

**Outcomes**  
A significant reduction of 20% in injury crashes equating to about 62 injury crashes per year on all 64 road sections combined.  
The decline in the number of injury crashes was related to the level of conformance with official warrants for the use of automatic speed enforcement (see notes).  
A decline of 26% in injury crashes was found on road sections conforming with both warrants. On road sections not conforming with any of the warrants, injury crashes declined by 5%.

**Notes**  
The warrants refer to crash rate (crashes/vehicle km) and crash density (crashes/km of road). Authors state frequency and duration of interventions unknown thus not possible to study the relationship between the intensity of enforce-
NO Nationwide  (Continued)

ment and the size of the effects on speed and crashes.
No before speed data was available to this study hence camera effects on speed are not assessed in the study.
Study controlled for possible confounding due to regression to the mean, changes in traffic volume and general trends in number of crashes.

NO Oslo

Methods  Controlled before-after study.
16 week study, two week 'before' period, six weeks enforcement, eight weeks 'after' period.
Continuous speed measurement at 12 sites for 16 weeks.
One experimental road divided into six sites, one control road divided into six sites.

Participants  One 35km long stretch of semi rural undivided two lane road in Norway with mainly 80km/h speed limits, but some 60km/h speed limits through small more densely populated communities.

Interventions  Five police patrols using stationary speed enforcement with observation units (mainly in unmarked hidden cars) measuring speed by radar or laser gun and 'stop' units using marked visible police cars to enforce.
Average nine hours of enforcement daily for six weeks

Outcomes  Reduction in speed relative to the control road.
Average speeds were reduced by 0.9 to 4.8km/h in both speed limit zones and for all times of day.
A time halo effect of up to eight weeks was shown.
The proportion of speeding drivers was reduced by 10% in both speed limit zones for all hours of day except the morning rush hours 6.00am to 9.00am.

Notes  The control road was close enough to have same weather conditions but the road ran through different communities hence migration of traffic not expected, however not ascertained.

NZ Christchurch

Methods  Controlled before-after study,
Study period 1988 to 1997.
Compared four years 'before' (1989 to 1992) data with four years 'after' data (1994 to 1997).

Participants  City of Christchurch, New Zealand.
Controls were matched non-camera sites in Christchurch.

Interventions  Progressive introduction of fixed overt speed cameras in 24 speed camera zones.

Outcomes  The outcome focus was all crashes rather than speed related crashes per se. Outcomes were results for all crashes and serious injury crashes. The latter combines both fatal and serious crashes.
A reduction of 9.17% (S.E 5.13%) in crashes and a significant 32.4% (S.E 12.51%) in serious injury compared to New Zealand overall after four years of the intervention was reported. It was also observed that the average difference between the 85th percentile and mean speed for the four years before and four years after intervention was only 0.8km/h.
NZ Christchurch  (Continued)

<table>
<thead>
<tr>

<table>
<thead>
<tr>
<th>Methods</th>
<th>Interrupted time series design with a comparison area. This study updates an earlier study and reports results from the first 2 years post implementation. The study period was from 1996 to 2002. Aggregated monthly crash data collected from November 1993. Speed data collected from July 1995 ongoing.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>The experimental area was the Midland Police Region of New Zealand, consisting of all 100km/h open roads in existing speed camera areas, 100km/h open roads generally, and 100km/h open roads with existing speed cameras plus new covert speed cameras. The comparison areas were 100km/h open roads in existing speed camera areas and 100 km/h roads generally, in the rest of New Zealand.</td>
</tr>
<tr>
<td>Interventions</td>
<td>This study as previously stated, updates an earlier study and coincided with an increase in enforcement, when covert cameras were added to the 100km/h roads which already had an overt speed camera program in place. For this study, overt speed cameras were used within designated speed camera sites up to 5km in length and on open roads, most cameras were mobile and operated from the rear of a (usually unmarked) police vehicle.</td>
</tr>
<tr>
<td>Outcomes</td>
<td>Over the first 2 years of the study mean speeds fell by 1.3 km/h and 85th percentile speeds fell by 4.3 km/h on open roads generally, compared with the rest of the country. Having controlled for season and general trends, injury crash outcomes in experimental areas relative to control areas were a net reduction of 11% (p= 0.03) in all crashes and 19% (p=0.002) in injury crashes on open roads across the region associated with the covert cameras, over and above the effects of the existing speed camera program. At speed camera sites reductions of 17% for crashes and 31% for injury crashes was reported.</td>
</tr>
<tr>
<td>Notes</td>
<td>This study updates an earlier publication. Speed cameras were introduced to New Zealand in 1993. This study involved an increase in camera operation and enforcement and builds on results from an earlier publication by the authors. Generally the cameras in comparison areas were overt. Experimental and comparison areas were matched for level of road safety advertising, quality of roads, road use, vehicle speeds prior to the trial and unemployment rates in the regions concerned. Speed measures were speed limit and number of km above the speed limit (in 5km/h bands) An enforcement tolerance of 10km/h over the speed limit accepted.</td>

</tr>
</tbody>
</table>
### US Arizona 1

| Outcomes | Both crash and speed outcomes reported. Only crash outcomes reported here as speed methods did not meet this review study criteria, in particular, before speed data was only collected during a ‘warning’ period. For crashes, a total crash reduction at enforcement zones of 44 to 55% was reported depending on which of the 3 analysis methods used, injury crash reduction of 46 to 56% with no reduction seen in rear-end crashes. |
| Notes | A good study regarding examination of crash effects, which took traffic flow, trend effects and RTM into consideration. Its biggest drawback was the short program period (9 months) More information on the comparison site would have been helpful. As the authors point out, it is important to examine spillover effects, and it is hoped that a much longer and detailed examination of speed camera enforcement in Scottsdale will contribute further to the evidence base. |

### US Arizona 2

| Methods | Before and after study design with control group. Nine month enforcement program. This study was conducted on an 8 mile corridor of the Scottsdale Loop 101 urban freeway, by comparison to the 6.5 mile corridor which was the subject of the Arizona 2009 study. The focus of this second Arizona study was speed outcomes only. Before speed data from December 2005 for about 2 months prior to enforcement at 4 collection sites on treatment corridor in addition to before speed data from 4 sites at comparison segments. The latter were on loop 101 near city of Glendale about 25 miles from Scottsdale. After data was collected at 6 weeks, 5 months and 12 months, and about 6 weeks after end of enforcement period. Results from 6 weeks and 5 months showed large speed reductions at Glendale (Comparison site) so a 2nd comparison location for analysis was added (non-Loop 101, routes 202 and 51) with 2 data collection points at 8 months and 12 months (December 2006) for the new comparison site before data for 'mean speeds' only, was obtained from the Arizona Department of Transportation therefore the mean speeds for all vehicles were used to compare speed between Loop 101 and non-Loop 101. |
| Participants | All motorised vehicles on an 8-mile segment of Arizona State Route 101, running through Scottsdale. |
| Interventions | Six fixed speed cameras at 6 stations in the enforcement zone positioned to enforce speed in either direction of travel, north and southbound. |
| Outcomes | The speed analysis compared Loop 101 vs Glendale section, Glendale vs non-Loop 101 roads and Loop 101 vs non-Loop roads. At the Scottsdale sites mean speeds decreased from 70 mph to about 65 mph. Reductions in mean speeds were similar for the Glendale sites. At the non-Loop 101 sites (where no before data was available) mean speeds fluctuated between 68 and 69 mph. The proportion of vehicles in excess of the tolerated speed limit decreased from 15% in the before period, to 1-2 % in the post implementation period at the Scottsdale sites. Similar reductions were seen at Glendale. The proportion of vehicles in excess of the speed limit at the non-Loop 101 sites was only measured for the final 2 collection periods. An increase in both mean speeds and proportion of drivers over the speed limit (from 1-2% to 12% at Scottsdale) was noted soon after speed camera enforcement was suspended. |
| Notes | The main weakness in this study was the need to use post hoc comparison sites because of what would appear to be significant spillover effects to the originally designated control sites at Glendale. Media coverage may also have confounded the enforcement effect. The fact that a lot of the positive speed reductions retracted soon after enforcement ended, is telling. |
### US Maryland

<table>
<thead>
<tr>
<th>Methods</th>
<th>Before and after study with comparison sites.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>This was the first speed enforcement program implemented in the state of Maryland. Residential streets with speed limits of 35mph or less and school zones in Montgomery county were targeted for enforcement.</td>
</tr>
<tr>
<td>Interventions</td>
<td>Initial enforcement carried out with 6 mobile cameras deployed in marked vans in 2007. The vans were in service from about 6 a.m. to 9 p.m. Monday through Saturday and rotated among 10 to 12 locations. During the first 6 months of enforcement, mobile cameras were deployed at about 60 locations in total and resulted in approximately 40,000 citations. Between the 5 and 6 month, the 6 mobile cameras were supplemented by 2 fixed cameras. 10 sites from 20 locations in Virginia were used as controls. Controls were matched for speed limits, road type and traffic flow. 10 similar non-enforced sites in Montgomery but with posted speed limits of 40 mph (which were thus ineligible for enforcement) and chosen randomly were examined for ‘spillover effects’. Six months of ‘before’ speed data and 6 months of ‘after’ speed data were used for the analyses.</td>
</tr>
<tr>
<td>Outcomes</td>
<td>Outcomes measured were mean speeds and percentage exceeding speed limit by &gt; 10 mph both for sites where cameras were deployed with warning signs installed, for sites where warning signs were installed but no cameras deployed and for the sites with 40 mph speed limits. Mean speed at the 5 sites (where cameras were deployed) decreased by 10% (range 5% -18%) The proportion of drivers travelling &gt; 10 mph above the speed limits declined by about 70% at locations with both warning signs and speed camera enforcement, 39% at locations with warning signs only and 16% on 40 mph residential streets with neither warning signs or speed cameras.</td>
</tr>
<tr>
<td>Notes</td>
<td>Changes in traffic volume were noted at some experimental sites which led to some sites accounting for a much larger sample size in the ‘after’ period compared to the ‘before’ period. To deal with this, overall statistics for each group of sites were computed as a weighted average of the statistics for each site, with weights defined as the proportion of vehicles observed at each site during the before period. Reasons for changes in traffic volumes were not discussed and whilst linear regression models were used to evaluate experimental site to site variability, it was not clear in this study if the comparison sites in Virginia changed in any way or remained similar during the study period.</td>
</tr>
</tbody>
</table>

### US North Carolina

| Methods | Controlled before-after study. Study period for crash data consisted of a before period of 4 years and an after period of 4 months between January 2000 and December 2004. Crash data consisted of police reported accidents. Speed data was collected approximately 10 months before speed camera implementation and approximately 3 months after enforcement began on all treatment and control corridors. |
| Participants | 14 high volume urban corridors in the city of Charlotte were enforced and evaluated. Eleven urban corridors in the same city were used as the control group for comparison. |
| Interventions | Mobile overt (marked vans)enforcement on legally designated corridors using warning signs within 1,000 feet (304.8 metres) of a parked enforcement vehicle and a ‘photo enforced’ warning notice beneath all speed limit signs on the enforced corridors. Speed data was collected using induction loops at 80 points along treatment corridors and at 40 points on control corridors. |
| Outcomes | Outcomes measured were total crashes, crash severity and crash type, mean,median, 85th percentile speeds, percentage of vehicles exceeding speed limit by >10 miles/hour and speed variance. 3 different crash data sets were analysed: Firstly using Hauer’s comparison group methodology ‘total crashes’ were analysed for period between January 2000 and December 2003. The 2nd data set from January 2003 to July 2004 was used to analyse if regression to the mean confounded the study results and the 3rd crash data sub-set analysed data from the 5 most heavily enforced corridors. |
US North Carolina  (Continued)

(accounting for 90.4% of the total citations) during the period September to December 2004. The aggregated change in total crashes was a statistically significant 12% reduction for treated corridors compared to the expected number, following enforcement with speed cameras. Results from the 2nd analysis showed a 11% statistically significant reduction in crashes in the treatment group and concluded that regression to the mean was 'likely negligible'. For the 5 heavily enforced corridors a statistically significant 14% reduction in crashes for treated corridors was reported compared to the expected number. The calculated relative crash ratio (RCR) for all crashes was 0.84 with 95%CI (0.76-0.93) day-time, and 01.04 (0.85-1.28) night-time. For injury crashes the calculated RCR with 95% CI was 0.78 (0.53-1.15) day-time and 0.75 (0.40-1.40) night-time. Using GLM and logistic regression models, reported mean speeds at treatment sites were a statistically significant 0.91 miles per hour (mph) reduction after the implementation of enforcement. The control sites showed a statistically non-significant 0.29 mph mean speed reduction. The results for 85th percentile speeds were a statistically significant 0.99 mph reduction at treatment sites and a non-significant 0.30 mph reduction at control sites. Two-tailed F-tests with significance level set at 0.05 were used to test for before and after periods and day versus night. The calculated relative speed ratio RSR (relative to control) was Day 0.99 (0.76-1.23) Night 0.98 (0.76-1.20) The percentage of vehicles exceeding the speed limit by 10 mph or more decreased by a statistically significant average of 55% at treatment sites compared to control sites which showed very little change. Forty eight percent of treatment sites compared to 30% of control sites showed a reduction in speed variance although considerable difference in speed variance at the different treatment and control sites was noted.

Notes

Efforts were made for controlling regression to the mean. Whether it succeeded on this count is debatable. Authors considered seasonality not to be a factor because comparison sites were subject to the same seasonal changes. Results can only be considered as a short term impact due to the short (only 4 months) 'after' data collection period. Although treatment and control sites were in the same city most of the high volume enforced corridors were in the treatment group. First time speed cameras used in North Carolina and was attended by a publicity campaign,which also involved a leaflet drop.

US Washington DC

Methods

Participants

Seven experimental sites and eight control sites. Combination of residential streets, school and work zones and arterial roads in seven police patrol districts in Baltimore.

Interventions

Five speed cameras in unmarked police cars deployed twice per week at each zone between 6.00am and 10.00pm, Monday to Saturday.

Outcomes

Mean speeds at experimental sites reduced by a significant 14% compared to control sites. The proportion of vehicles exceeding the speed limit by more than 10mph decreased 82%.

Notes

Characteristics of control sites not clearly described.

None known.

SOURCES OF SUPPORT

Internal sources
- The University of Queensland (infrastructure), Australia.

External sources
- Motor Accident Insurance Commission, Australia.
- SWOV, Netherlands.

The librarians at the Institute for Road Safety Research (SWOV) in the Netherlands ran a search for us in order to capture any relevant studies from the Nordic countries possibly not published in English.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

This systematic review is based on the specifications within the protocol and follows on as a natural expansion, with no differences or conflict between protocol and review. However, the title used for the protocol 'Speed enforcement detection devices for preventing road traffic injuries' has been changed to a less cumbersome and easier to find title for the review, and is now titled 'Speed cameras for the prevention of road traffic injuries and deaths'.
